Book Review Editor: Dale W. Adams, Ohio State University

Technical Editor: Martha A. Luzader, P.O. Box 189, Rockville IN 47872-0189. Phone (317) 344-1426

Editorial Assistant: Phyllis Blackford

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to:

Peter J. Barry, Editor
Department of Agricultural Economics
University of Illinois
305 Mumford Hall
1301 W. Gregory Drive
Urbana, Illinois 61801

Effective 1 February 1991, submissions of new manuscripts should be sent to: Steven T. Buccola and Richard M. Adams, Co-editors, Department of Agricultural and Resource Economics, Oregon State University, Corvallis, OR 97330.

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor: Otto Doering, Department of Agricultural Economics, Krannert Building, Purdue University, West Lafayette, IN 47907.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged. The *American Journal of Agricultural Economics* (ISSN 0002-9092) is published monthly in February, May, August, November, and December by the American Agricultural Economics Association, 80 Heady Hall, Iowa State University, Ames, Iowa and printed by Edwards Brothers, Inc., Ann Arbor, MI. Second-class postage is paid at Ames, Iowa, and additional mailing offices. Postmaster: Send address changes to the American Journal of Agricultural Economics, 80 Heady Hall, Iowa State University, Ames, Iowa, 50011-1070.

Subscription

Subscription cost is \$65 per year plus foreign postage; members receive copies as part of their membership fee of \$60 per year.

Copyright 1991 American Agricultural Economics Association. Any article or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the written permission of the editor.

Formally Testing the Present Value Model of Farmland Prices

Barry Falk

This paper applies recent statistical developments in the study of stock market price movements to study the plausibility of the constant expected returns version of the present value model as an explanation of farmland prices. Using Iowa farmland price and rent data over the 1921–86 sample period, formal test results indicate that, although farmland price and rent movements are highly correlated, price movements are not consistent with the implications of this model. There appear to be persistent predictable excess positive and/or negative returns in the Iowa farmland market.

Key words: efficient market hypothesis, farmland prices, present value model.

Farmland prices in the United States have undergone occasional periods of sustained booms followed by sustained busts. The most recent example was the boom of the 1970s and the bust of the 1980s. Melichar (1984) has identified four other price cycles of this sort over the last two hundred years. The recent major cycle in farmland prices has generated considerable interest in the determination of farmland prices. Papers by Alston, Melichar (1979), Burt, and Featherstone and Baker are especially relevant to this study.

The financial economics literature also has displayed a surge of interest in evaluating the extent to which financial asset prices can be explained in terms of rational evaluations of current and expected asset income. This literature began with studies by Shiller and by Leroy and Porter. The current state of this literature is summarized by DeBondt and Thaler and by West (1988a).

The fundamental economic questions addressed in these two lines of literature are essentially the same. First, how much of an asset's price movement is caused by factors which determine the fundamental value of the asset,

i.e., current and expected future returns and discount rates? Second, do these factors account for asset price movements in a rational manner? In contrast to the existing studies of farmland prices, the financial economics literature has developed new statistical tests (such as Shiller's variance bounds tests) designed especially to help answer these kinds of questions; and it has utilized recent developments in the study of non-stationary time series, such as the application of unit root and cointegration theory.

The purpose of this paper is to apply statistical developments in the study of stock market price movements to study farmland prices and formally test the validity of the constant discount rate version of the present value model of farmland prices. A strategy developed by Campbell and Shiller (1987) will be applied to study the behavior of annual Iowa farmland prices over the 1921–86 sample period. The Iowa farmland market is used for several reasons. First, relatively long time series on Iowa farmland prices and rents are available. Second, Iowa farmland is relatively homogenous, primarily suited for growing corn and soybeans, and its value has not been strongly influenced by non-agricultural uses. Finally, an active cash rental market provides readily available cash rent data for Iowa farmland.

The remainder of the paper provides a review of the literature on farmland prices, a description of Campbell and Shiller's procedures, a description of the data, the empirical results and a discussion of their implications.

Barry Falk is an associate professor of economics, Iowa State University.

Journal Paper No. J-14034 of the Iowa Agriculture and Home Economics Experiment Station Project No. 2911.

The author gratefully acknowledges Michael Duffy's help in obtaining the data, the research assistance of Cheol-Soo Park, and helpful comments from anonymous referees and Robert Shiller.

Review of Related Literature

The modern study of farmland price determination goes back at least to the 1960s with the efforts of Herdt and Cochrane, Reynolds and Timmons, and Tweeten and Martin to model land prices in a simultaneous equations framework; but the inability of these models to explain subsequent land prices (as shown by Pope et al.) discouraged further efforts along these lines. Much of the problem in this kind of approach involves the inelasticity of farmland quantity, so that attempts to identify a classic supply equation in this market may not be appropriate. Since the 1970s, attention turned to the role of demand forces in explaining land price movements.

Klinefelter, and Castle and Hoch attempted to explain land prices in terms of expected net rents and expected capital gains as though these two components of land price are distinct from one another. Although it is possible that capital gains are driven by speculative forces or by forces unrelated to rents (i.e., by "sunspots"), capital gains can also result from a growing stream of net rents (Melichar 1979). More recent literature has focused on the behavior of land prices in a manner consistent with the conventional present value formulation.

Consider the conventional present value formulation of farmland price determination:

$$(1) \quad Y_t = \beta \sum_{s=0}^{\infty} \beta^s E[y_{t+s}|I_t],$$

where Y_t is the real value per acre of homogeneous farmland at the start of period t , y_t is the real net rent per acre of farmland in period t (paid at the end of period t), and β is a discount factor which is equal to $1/(1+r)$ where r is the real interest rate, so that $0 < \beta < 1$. Expressions of the form $E[X_{t+s}|I_t]$ denote the market's expectation of X_{t+s} formed at the start of time t on the basis of its information set at that time. This model assumes a constant real interest rate and ignores the differential tax treatment of capital gains and rental income. It can be derived as the stable forward solution to the following difference equation which is a form of the efficient markets hypothesis:

$$(2) \quad Y_t = E[Y_{t+1} + y_t|I_t]/(1+r).$$

The fact that (1) can be derived as the solution to (2), solving (2) forward recursively, makes clear the point that capital gains can be ex-

plained in theory as the capitalization of expected future rents.

Melichar (1979) and Alston assume that net rents are expected to grow at the constant rate g so that $E[y_{t+s}|I_t] = (1+g)^s y_t$ for all t . In this case, the value of Y_t implied by (1) simplifies to $Y_t = (1/(r-g))y_t$, provided that r is larger than g . According to this model, land prices should grow at the same rate as rents grow. Using U.S. aggregate data since 1950 (Melichar) and data from eight midwestern states since 1960 (Alston), these authors compare average annual growth rates of real land prices and real returns to land ownership over various sample periods and find that these averages are close to one another. They conclude that most of the variation in farmland prices over time can be attributed to changes in net rental income.

Burt assumes that, although (1) may provide a reasonable description of the long-run or steady-state equilibrium behavior of farmland price determination, it is less likely to be an appropriate representation of the short-run behavior of farmland prices. However, net rents may still be the primary factors determining land prices. To quantify this view Burt assumes that Y_t is determined according to the distributed lag model,

$$(3) \quad Y_t = (\alpha y_t^{b_0} y_{t-1}^{b_1} \dots) u_t,$$

where $\log u_t$ is a zero-mean stationary process, α is the inverse of the real interest rate, and b_0, b_1, \dots are fixed parameters which sum to unity.¹ He estimates a restricted version of (3) and then shows according to a variety of descriptive criteria that it can provide a good in-sample fit to Illinois annual farmland price data over the period 1960-84 and that it has good out-of-sample predictive power (treating out-of-sample rents as known *ex ante*). He concludes (p. 25) that his results "strongly support the view that rents are the underlying source of value, and there is little evidence that farmland prices are driven by the same speculative forces as those for nonincome-earning assets such as precious metals and stones." He also concludes, however, that there are aspects of the relationship between land prices and rents which are not consistent with the present value mode.

In contrast to Alston, Burt, and Melichar (1979), Featherstone and Baker conclude that

¹ Burt assumed that in the long run rents converge to the constant y^* . Because the unconditional expectation of u_t is equal to one and the b 's sum to one, it follows from (3) that Y_t will converge to αy^* , which is consistent with (1) under the assumption that y_t is equal to y^* for all t .

net rents cannot explain a substantial portion of farmland price movements, suggesting that there may be purely speculative forces in farmland price determination. Furthermore, to the extent that farmland prices do respond to unanticipated changes in current and expected future rents, the responses are too large and protracted to be consistent with a present value formulation. These conclusions are based on an application of Sims's innovation accounting method to an estimated vector autoregression of U.S. annual real farm asset values, real net returns, and real interest rates.

In summary, a review of the recent literature indicates that a variety of strategies have been used to evaluate the plausibility of the present value model of farmland prices with mixed conclusions. However, none of the strategies incorporate a formal test of the restrictions that the model imposes on the data. The main purpose of this paper is to fill that gap.

A Strategy for Testing the Present Value Model of Farmland Prices

The purpose of this section is to explain the statistical procedures that will be used to evaluate whether Iowa farmland prices evolve according to the present value relationship. In contrast to the literature reviewed above, these procedures will lead to formal tests of the model. The strategy is fully described by Campbell and Shiller (1987) and thus will be only briefly reviewed here.

We begin with the assumption that the present value model (1) is a valid representation of the relationship between real farmland prices at the start of year t and current and expected future real net rents, where current rent accrues to the landowner at the end of period t . The model assumes that the discount rate β and, hence, the real interest rate r are constants.² The market's expectations are assumed rational so that $E[y_{t+s}|I_t]$

is interpreted as the mathematical conditional expectation of y_{t+s} given the information set I_t . The only restriction imposed on this information set is that it contains at least Y_t, Y_{t-1}, \dots and y_t, y_{t-1}, \dots .³ Let H_t denote this subset of I_t .

Real net rent time series show a tendency to grow over time; therefore, real net rents are nonstationary in their mean. One common modeling approach is to assume that the process is stationary around a nonstochastic linear trend. An alternative assumption is that the process is difference stationary, i.e., the first differences of the process form a stationary process. The choice of assumption has important statistical and economic implications.⁴ For example, an unanticipated change in a trend stationary process has only a temporary effect on the process, whereas an unanticipated change in a difference stationary process has a permanent effect. Assume for now that net rents evolve as a difference stationary process.

If the present value model is correct and if net rents evolve as a difference stationary process, then it can be shown (Campbell and Shiller 1987) that Y_t is also a difference stationary process. One battery of tests of the present value model will consist of Dickey-Fuller tests to determine whether the pattern of stationarity between land prices and rents is consistent with this implication of the present value model.

Next, define a new variable S_t called the spread which is the linear combination of Y_t and y_t given by

$$(4) \quad S_t = Y_t - \theta y_t,$$

where θ is determined by the discount factor according to $\theta = \beta/(1 - \beta)$; thus, it equals the reciprocal of the real interest rate. Campbell and Shiller show that if the present value model is correct, then the spread can be interpreted as the rational forecast of the present value of all future changes in net rents.

³ This restriction requires an assumption that cash rent payments in year t are known at the start of the year which seems reasonable if these payments are based upon contracts written at the start of that year. Campbell and Shiller (1987) show how to modify their procedures if these payments are not determined until later in the year. All of the empirical analysis in this paper was also executed in terms of that modified procedure. The results were not sensitive to these modifications.

⁴ Whether economic time series are better characterized as difference stationary processes or as trend stationary processes has been an important issue in studying the relationship between stock market prices and dividends (West 1988a). It is also at the core of the current debate in macroeconomics over whether real business cycle models or monetary business cycle models offer a more plausible explanation of the business cycle. At this point the prevailing view appears to favor the assumption of difference stationarity.

² Burt also assumed that the discount rate is constant over time. Although Featherstone and Baker incorporated observed real interest rates in their VAR analysis to account for a time-varying discount rate, changes in the real interest rate had only a marginal effect on the time path of land prices. While it is possible to allow for a time-varying discount rate (e.g., Campbell and Shiller 1988), this requires additional less appealing restrictions on the model's structure. Furthermore, the constant discount rate version of the model is more convenient to work with analytically and empirically. It should not be abandoned without compelling empirical arguments. The absence of a formal test of the constant discount rate version of the present value model of farmland prices, prior to this paper, indicates that such arguments do not yet exist.

The present value model imposes testable cross-equation restrictions on the vector autoregressive representation of the change in $y_t(\Delta y_t)$ and the spread S_t . Specifically, if Δy_t is assumed stationary then the present value model implies that S_t will be stationary too. Then, under general side conditions, Δy_t and S_t will have a vector autoregressive representation of the form

$$(5a) \quad \Delta y_t = a(L)\Delta y_{t-1} + b(L)S_{t-1} + u_{1t}$$

$$(5b) \quad S_t = c(L)\Delta y_{t-1} + d(L)S_{t-1} + u_{2t},$$

where $a(L)$, $b(L)$, $c(L)$, and $d(L)$ are p th-order polynomials in the lag operator L , i.e., $a(L) = a_0 + a_1L + a_2L^2 + \dots + a_pL^p$, where $L^p x_t \equiv x_{t-p}$, and u_{1t} and u_{2t} are zero-mean, constant variance, and serially uncorrelated processes which are mutually uncorrelated at all leads and lags, except that $E[u_{1t}u_{2t}]$ may be nonzero. The present value model and the stationarity of Δy_t imply that this VAR will be characterized by S_t Granger-causing the Δy_t process, so that some of the elements of $b(L)$ will be nonzero, and by the following cross-equation restrictions: $c_i = -\theta a_i$, $i = 1, 2, \dots, p$; $d_1 = (1/\beta) - \theta b_1$; and $d_i = -\theta b_i$, $i = 2, \dots, p$.

The restriction that S_t Granger-causes the Δy_t process means that, given past changes in net rents, past values of the spread add useful information in forecasting future changes in rents. Recall that the spread can be interpreted as an optimal forecast of a weighted average of future changes in net rents based upon the market's complete information set. Any information in this set beyond lagged values of y_t itself that is useful in forecasting future changes in y_t will be reflected in the VAR by a nonzero $b(L)$. This situation is formally proven by Campbell and Shiller (1987, footnote 7).

To interpret the cross-equation restrictions define a new variable, x_t , according to

$$(6) \quad x_t \equiv Y_t + y_{t-1} - (1+r)Y_{t-1}.$$

Thus, according to (2), x_t measures the *ex post* excess return to holding land in period $t - 1$. According to the present value model (1), it can be shown that another representation of x_t is

$$(7) \quad x_t = Y_t - E[Y_t|I_{t-1}].$$

This follows because the present value model is constructed to rule out *ex ante* excess returns and the only component of x_t which is assumed to be unknown at the start of period $t - 1$ is the end-of-the-period price of land, Y_t . Thus, x_t can also be interpreted as the unpredictable com-

ponent in the price of land in period t based upon the market's complete information set in period $t - 1$, I_{t-1} . Because this information set contains, by assumption, at least the set of past prices and returns, H_{t-1} , it follows by the law of iterated expectations that $E[x_t|H_{t-1}] = 0$ for all t . In other words, according to the present value model, current excess returns ought to be unpredictable based upon past prices and rents. The cross-equation restrictions on the VAR coefficients account for this implication of the model.

In summary, if land prices evolve according to the present value model (1) where market expectations are formed rationally on the basis of an information set which contains at least past prices and rents and if rents evolve as a difference stationary process, then the model has testable implications of two types. First, it implies that land prices also evolve as a difference stationary process. Second, the theory imposes Granger-causality and cross-equation restrictions on the vector autoregressive representation of the spread and the changes in rents.

The Data

In this paper Y_t is measured as the estimated average value of an acre of Iowa farmland in year t and y_t is measured as the estimated average annual cash rent per acre of Iowa farmland in year t . Each series is divided by the corresponding year's consumer price index (1967 = 100). The sample period is 1921–86.

The time series of average annual prices per acre of Iowa farmland was constructed by splicing the U.S. Department of Agriculture's (USDA) farm real estate value, by state, series (1921–49) with Iowa State University Extension Service's Iowa land value series (1950–86). The latter series is considered to be a more reliable measure of average Iowa land prices since 1950. The differences between the two series since 1950 are not large enough to substantially affect the results of this study. The USDA's series is described more fully in Barnard and Hexum. The Iowa Land Value Survey data are described more fully in the Iowa State University Extension Service's FM-1825 publications.

The theoretical model assumes that Y_t is the price at the beginning of the period. It is not possible to associate a particular part of the year to which the USDA price measure most closely corresponds. The Iowa Land Value Survey reports end-of-period prices (i.e., November of year t). Although the results reported in this paper

treat all of these prices as beginning-of-the-year prices, the empirical procedures were also done using the price reported in year $t - 1$ (divided by the price index for year t) to form the measure of Y_t . The latter results (available from the author) are less consistent with the present value model.

The cash rent time series used to form y_t are average dollar rents paid per acre for the rental of whole Iowa farms (i.e., land and buildings). These data are estimates produced by the Iowa Agricultural Statistics Service (formerly known as the Iowa Crop and Livestock Reporting Service). They are published by the USDA's Economic Research Service. Using cash rents may have several shortcomings. Several types of farmland leasing contracts are common in Iowa: crop-share leases, cash leases, and combinations of the two. Perhaps a systematic relationship between the quality of land and the nature of the leasing arrangement biases the cash rent data as a measure of return per acre. Second, factors other than the cash rent influence the landowner's net return, such as owner-borne maintenance costs, property taxes, and insurance premiums. Nevertheless, the active cash rent market in Iowa suggests that the use of cash rents to index returns may be less of a problem than it would in other parts of the country.

The cash rent and cash price series were converted to real rent and price series, respectively, by dividing each series by the CPI (all items, 1967 = 100) for that year. The CPI data were collected from the U.S. Commerce Department's publication *Historical Statistics of the United States: Colonial Times to 1970* (1921–70) and from various issues of the Commerce Department's *Business Statistics*. The choice of an appropriate deflator is problematic. The CPI was selected because it is the purchasing power of consumption goods that motivates portfolio allocation choices. It is unlikely that the results will be sensitive to the use of other deflators.

Figure 1 is a time series plot of Y_t and y_t , where the latter is weighted by a constant to provide a common scale. Both price and rent are characterized by positive long-run trends which were interrupted by the major declines during the 1920s and early 1930s and again in the late 1970s and early 1980s. The similarity in the general shapes of the two series is confirmed by a sample cross-correlation statistic of 0.90. However, casual observation suggests that prices fall faster than rents when both are falling and prices rise faster than rents when both are rising. In other words, price movements appear to be more volatile than

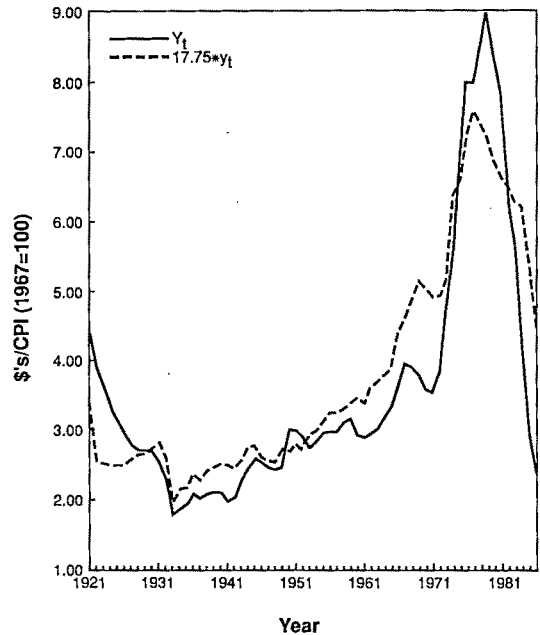

Figure 1. Price (Y_t) and weighted rent ($17.75*y_t$)

rent movements. This paper will formally test whether prices are excessively volatile relative to the predictions of the present value model.

Test Results

Unit Root Tests

The test strategy discussion indicated that the tests are not valid unless real rents evolve as a difference stationary process. In this case, the theory implies that land prices will also evolve as a difference stationary process. Thus, the first test is whether land prices and rents evolve as difference stationary processes rather than trend stationary processes.

Consider the following representations of rents and prices, respectively,

$$(7) \quad \Delta y_t = \alpha + \delta t + \phi y_{t-1} + u_t, \text{ and}$$

$$(8) \quad \Delta Y_t = \alpha' + \delta' t + \phi' Y_{t-1} + v_t,$$

where u_t and v_t are zero-mean, constant variance, and serially uncorrelated disturbance processes. Under the null hypothesis that $y_t(Y_t)$ is difference stationary the parameters δ and ϕ (δ' and ϕ') are jointly equal to zero. Under trend stationarity, δ (δ') is unrestricted and ϕ (ϕ') is between zero and negative one. The Dickey-Fuller test of the null hypothesis is based upon

a comparison of the standard t -statistic obtained from a regression of Δy_t on a constant, t , and y_{t-1} (and of ΔY_t on a constant, t , and Y_{t-1}) and the critical values of this statistic under the null hypothesis. The distribution of the t -statistic under the null hypothesis is nonstandard, and so the critical values cannot be extracted from the usual tables. The critical values for the non-standard distribution are available in Fuller (p. 373).

Table 1 shows the Dickey-Fuller test results. The null hypothesis that land prices and rents are stationary in their respective first differences cannot be rejected.⁵ Thus, the crucial precondition of the testing strategy and one of the subsequent implications of the present value model are assumed to be satisfied.

Testing the VAR Restrictions

The next step is to test the restrictions that the present value model imposes on the VAR representation of Δy_t and S_t . The process S_t is not directly observable since according to (4) it depends upon θ , the reciprocal of the unobservable constant real interest rate appropriate for discounting future income. However, a consistent estimator of θ is the regression coefficient on y_t in a regression of Y_t on y_t and a constant.⁶ This

estimate of θ is 17.75, which implies an annual real interest rate of 5.6%.⁷ Based upon this estimate of θ we can construct a consistent estimator of S_t according to (4).

The unrestricted VAR representation of Δy_t and S_t was assumed to have a third-order lag structure based upon the results of Sims' (1980) modified likelihood ratio test. Table 2 contains a summary of the VAR, which was estimated by OLS, including the results of tests of the restrictions implied by the present value model. The R^2 of the Δy equation implies that over 50% of the change in real cash rents is predictable on the basis of its own past changes and the past history of the spread. The Granger-causality test cannot reject the hypothesis that the spread Granger-causes changes in rents, which is an implication of the present value model provided that the market uses information other than past values of y_t to forecast current and future changes in y_t .

The cross-equation linear restrictions implied by the present value model also are tested. These restrictions correspond to the restriction that excess returns in the Iowa farmland market are not predictable and, hence, that systematic profit opportunities do not typically exist. Wald tests were executed in RATS based upon White's heteroskedasticity-consistent covariance matrix estimator. This estimator accounts for the difference between the variances of the two disturbance processes in the VAR as well as the contemporaneous correlation between those two processes. The model was estimated without restricting the mean of either Δy_t or S_t . However, the present value model implies that the unconditional mean of the spread is zero. Therefore the cross-equation restrictions were tested without restricting the mean of S_t , and then these restrictions were tested along with this zero restriction. Both versions of the test reject the cross-equation restrictions implied by the present value model at the 1% level of significance.⁸

⁵ A modified version of the Dickey-Fuller test proposed by Said and Dickey was applied to account for possible serial correlation in the disturbances in (7) and (8). A version of the test developed by Phillips and Perron was applied to account for possible serial correlation or heteroskedasticity in these disturbances. The results consistently support the null hypothesis of difference stationarity. The possibility of a second unit root in each series was also considered and rejected. This is important because Diba and Grossman have shown that if y_t has exactly one unit root then the presence of at least two unit roots in Y_t is a necessary condition for deviations from the present value model because of a rational bubble. Further discussion and results pertaining to the unit root issue are available in Falk.

⁶ This follows because one way to interpret the implication of the theory is that Y_t and y_t are cointegrated processes of order (1, 1). See Campbell and Shiller (1987) or, for a more complete discussion of cointegrated processes, see Engle and Granger.

Table 1. Dickey-Fuller Unit Root Tests

Unrestricted model: $\Delta z_t = \alpha + \delta t + \gamma z_{t-1} + u_t$

$$H_0: \delta = \gamma = 0$$

(z_t is difference stationary)

z_t	τ
y_t	-1.25
Y_t	-2.50

Note: τ is the " t -statistic" on the regression coefficient on z_{t-1} in the unrestricted model. H_0 is rejected at the 10% level of significance if $\tau < -3.18$. See the third section of Fuller's table 8.5.2.

Further Analysis

It is possible that the statistical rejection of the implications of the present value model is not of economic importance. That is, the statistical

⁷ The mean annual rate of return in this market, measured as the sample mean of $(Y_{t+1} - Y_t + y_t)/Y_t$, was 5.7%.

⁸ The distribution of the Wald statistic under the null hypothesis is based upon asymptotic distribution theory. Campbell and Shiller's (1989) Monte Carlo experiments on the small-sample properties of a similar test statistic indicate a slight tendency to reject the null too often for a given test size.

Table 2. Testing the Restrictions of the VAR Representation of Δy_t and S_t

Sample Period: 1921–1986, annual observations

Lag Length = 3

Granger-Causality Tests—

 Δy equation $R^2 = .522$; S Granger-causes Δy at the .00001 level. S equation $R^2 = .825$; Δy Granger-causes S at the .018 level.

Wald Tests of the Cross-Equation Restrictions—

without the mean restriction: $\chi^2(6) = 38.27$, p -value = .99E-06with the mean restriction: $\chi^2(7) = 39.38$, p -value = .17E-05.

failure of the present value model implies that the absence of systematic excess profit opportunities in the Iowa land market is quite unlikely. However, the magnitude of the profit opportunities may be small enough to be disregarded. In this section an argument is made that the statistical results reported above are the result of economically important deviations from the present value model.

Let S'_t denote the expected present value of all future changes in rent conditional upon current and past prices and rents, multiplied by the constant θ :

$$(9) \quad S'_t = \theta \sum_{i=1}^{\infty} \beta^i E[\Delta y_{t+i} | H_t],$$

where the information set H_t contains current and past values of land prices and rents. Based upon the unrestricted VAR representation of Δy_t and S_t given by (5) it can be shown (Campbell and Shiller, 1987, p. 1068) that

$$(10) \quad S'_t = \theta h' \beta A (I - \beta A)^{-1} z_t,$$

where h' is the $1 \times 2p$ row vector $[1 \ 0 \ \dots \ 0]$; I is the $2p \times 2p$ identity matrix; $z_t = [\Delta y_t, \dots, \Delta y_{t-p+1}, S_t, \dots, S_{t-p+1}]'$; and A is the $2p \times 2p$ companion matrix of the VAR, i.e.,

$$A = \begin{bmatrix} a_1 & a_2 & a_3 & \dots & a_{p-1} & a_p & \dots & b_1 & b_2 & b_3 & \dots & b_{p-1} & b_p \\ 1 & 0 & 0 & \dots & 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ 0 & 1 & 0 & \dots & 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 1 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ c_1 & c_2 & c_3 & \dots & c_{p-1} & c_p & \dots & d_1 & d_2 & d_3 & \dots & d_{p-1} & d_p \\ 0 & 0 & 0 & \dots & 0 & 0 & \dots & 1 & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & 0 & \dots & 0 & 0 & \dots & 0 & 1 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 0 & 0 & \dots & 0 & 0 & 0 & \dots & 1 & 0 \end{bmatrix}$$

Thus, S'_t can be estimated based upon the previous estimates of θ (and, hence, β) and the VAR coefficients.

The observed spread, S_t , and the theoretical spread, S'_t , are related according to

$$(11) \quad S'_t - S_t = \sum_{i=1}^{\infty} \beta^i E[x_{t+i} | H_t],$$

where x_t was defined previously as the excess return in period t to land ownership.⁹ Thus, the difference between the theoretical spread and the actual spread measures the expected present value of predictable excess future returns. According to the present value model, predictable excess returns should be zero, i.e., the actual and theoretical spreads should be equivalent. Therefore, sampling error aside, observed deviations of the actual spread from the theoretical spread indicate persistent predictable excess positive and/or negative returns in the Iowa farmland market.

Figure 2 indicates a strong degree of negative correlation between the time-series plots of S_t and S'_t . The sample correlation between these two time series is $-.86$ with a numerically estimated standard error of $.07$. The extreme negative correlation is too large to be attributable to sampling error or to measurement errors associated with the use of cash rents to measure net returns to land ownership.

It is interesting to compare these results with those of Campbell and Shiller in their study of stock market prices. They also rejected the cross-equation restrictions on the VAR. When they used the sample mean annual rate of return on stock ownership (8.2%), they computed a correlation between the theoretical and actual spreads of $-.46$. Thus, the results for the U.S. stock market and the Iowa farmland market are consistent with one another and suggest the presence of some common underlying tendencies. This consistency also helps to confirm the value

⁹ Equation (11) can be derived from equations (4), (6), and (10).

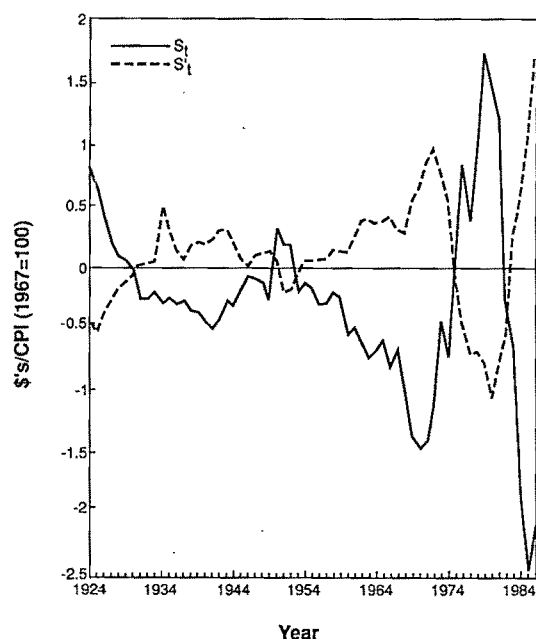

Figure 2. Theoretical spread (S'_t) and actual spread (S_t)

of applying this analytical approach to the study of farmland prices.

On the basis of figure 2 it appears that the statistical rejection of the present value model is attributable to sustained periods of positive (or negative) expected excess returns to holding Iowa farmland. Furthermore, the sign and magnitude of these expected excess returns vary directly with the sign and magnitude of the theoretical spread (and inversely with the sign and magnitude of the actual spread). Loosely speaking, Iowa farmland prices tend to be unusually high (low) when the present values of expected future changes in rents are unusually low (high).

One possible explanation of these features of the data is that traders in the Iowa farmland market act in a myopic manner. Suppose that the changes in rents are positively autocorrelated and a sequence of decreases in real rents (relative to the mean change) occurs. The stationarity of these first differences means that the sequences of decreases will subsequently be offset by a sequence of increases before stabilizing at their mean value. If, however, traders ignore the tendency of runs of decreases to be offset by runs of increases and instead assume that recent changes are permanent or will be exacerbated over time, then the price of land will be driven downward. Although the theoretical spread will

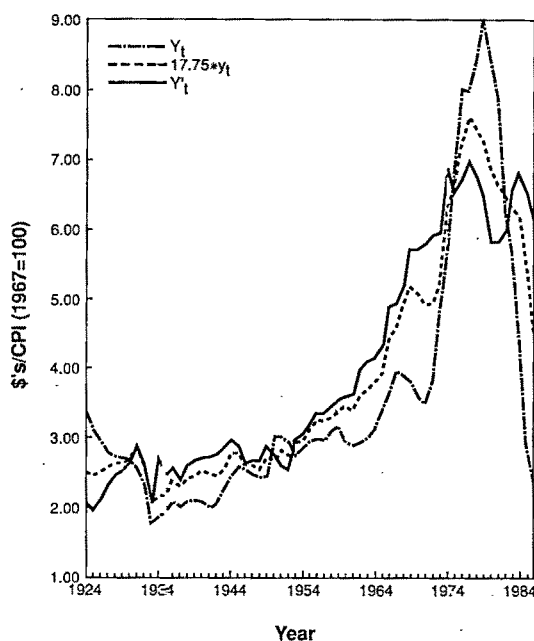

Figure 3. Price (Y_t), weighted rent ($17.75*y_t$), and rational price (Y'_t)

be positive due to the transitory fall in rents, the actual spread will be negative because of the erroneous perception that the fall is permanent.

Another view is offered by comparing the behavior of the actual price, the *ex ante* rational price, and actual rents.¹⁰ Figure 3 contains a plot of the actual real price (Y_t), the *ex ante* rational price (Y'_t) derived according to $Y'_t = S'_t + \theta y_t$, and real rents weighted by the constant θ .¹¹ Notice that Y'_t tends to move less than proportionally with respect to changes in y_t , while Y_t tends to move more than proportionally with respect to such changes. In other words, Iowa farmland prices show a tendency to overreact to movements in rents. These tendencies are especially apparent during the most volatile periods of the sample period. They suggest that θy_t will tend to lie between Y_t and Y'_t , and, therefore, S_t will be negatively correlated with S'_t .

Concluding Comments

Recent studies of farmland prices have suggested that net rents are the primary determinant

¹⁰ This explanation and the use of figure 3 to support it were suggested to me by Robert Shiller.

¹¹ The rational price would prevail according to (4) if the theoretical spread (S'_t) and the actual spread (S_t) are equal to one another, i.e., in the absence of exploitable profit opportunities.

of farmland prices (Alston, Burt, and Melichar) but that these prices tend to overreact to recent changes in rents (Featherstone and Baker). This paper has utilized statistical techniques developed in the financial economics literature to study the relationship between financial asset prices and returns in order to assess these conclusions. Using Iowa farmland price and rent data over the 1921–86 sample period, the results indicate that although farmland price and rent movements are highly correlated, price movements are much more volatile than rent movements. A formal test of the cross-equation restrictions imposed by the present value model of farmland price determination failed to support these restrictions and, therefore, the model itself. Subsequent analysis suggested that the model's statistical failure is attributable to economic factors rather than to measurement and sampling error.

One possible explanation of the model's failure is that the Iowa farmland market is characterized by rational bubbles. A rational bubble reflects a tendency for price to deviate from its fundamental value in a nonstationary manner as a result of self-fulfilling beliefs that the price depends on a variable (or a group of variables) that may be intrinsically irrelevant with respect to the asset's fundamental value (e.g., Diba and Grossman). The presence of such bubbles does not appear to characterize the U.S. stock market, and Falk has argued that they seem unlikely in Iowa farmland prices as well.

Another possible explanation that is consistent with rational investor behavior is that the discount rate in the present value model is time varying. Shiller, West (1988b), and Campbell and Shiller (1988) concluded that this explanation cannot reconcile the behavior of stock market prices and dividends with the present value model. Nonetheless, further research could explore this issue for farmland valuation.

Perhaps the most promising direction for future research into the determination of farmland prices is the study of nontraditional, or fad, models. In these models (e.g., Summers), prices tend to overreact to movements in current and recent returns. Although price has a tendency to return ultimately to its fundamental value (in contrast to a rational bubble), it may be years before this return occurs. In the meantime, systematic profit opportunities exist in the market although they may be difficult to detect and exploit.

Campaign Contributions and House Voting on Sugar and Dairy Legislation

David G. Abler

In this article, I explore the determinants of campaign contributions by sugar and dairy producer PACs and their role in voting on sugar and dairy legislation in the U.S. House of Representatives. Contributions and voting may be linked in two ways. First, a group can buy votes from a legislator who would otherwise not support the group. Second, it can help elect a legislator who is ideologically predisposed to support the group. Results indicate that the first linkage is not important. Virtually the entire observed association between money and voting is a result of the second linkage.

Key words: farm groups, farm legislation, PACs, rent seeking, voting.

Growing evidence demonstrates the simultaneity between economic conditions and agricultural policy outcomes (Gardner, Lopez, Honma and Hayami). Agricultural policy affects economic conditions in ways that have been exhaustively studied. Economic conditions affect policy because they influence the gains or losses to various political influence groups from a given program and, in turn, the extent to which they lobby for or against that program. In light of the dominant role of policy in agriculture in most countries, an understanding of economic events in agriculture requires an appreciation of both parts of this simultaneous relationship.

Most of the influential farm groups have significant membership in only a small number of districts in the U.S. Congress, and yet they receive sizable political favors. A study of the 1985 farm bill (Abler) found vote trading used heavily by tobacco, sugar, peanut, and dairy farmers, with other farm groups trading votes to a lesser extent. At the same time, many farm groups have political action committees (PACs) that give campaign contributions as part of their rent-

seeking activities. The purpose of this article is to explore the determinants of campaign contributions by sugar and dairy producer PACs and their role in voting on sugar and dairy legislation in the U.S. House.

A group that gives money to a legislator obviously expects something in return. The return can occur in two ways. First, the group can buy votes from a legislator already in office, one who would not support the group without the contribution. Second, it can use contributions to help elect a legislator who, because of personal ideology or some other reason, is predisposed to support the group. If elected, this legislator supports the group regardless of the amount it contributed. The first linkage is considered the most important, but there is little hard evidence one way or another. This article tests if either or both of these linkages is present.

Votes in the House on sugar and dairy amendments to the 1985 farm bill are studied. Of the farm groups, only sugar, dairy, cotton, and cattle producers give campaign contributions to enough representatives to do statistical work in which contributions is a dependent variable. Of these four groups, only sugar and dairy farmers faced amendments specifically directed at them. A group-specific amendment is necessary for a clean test of linkages between contributions and voting. With a motion affecting several groups, the impact of each group on a representative's vote must be distinguished.

David G. Abler is an assistant professor, Department of Agricultural Economics and Rural Sociology, Pennsylvania State University.

The author wishes to thank Cathy Hamlett, Spiro Stefanou, and anonymous *Journal* referees for many helpful suggestions on earlier drafts of this article.

The Model

To analyze the determinants of campaign contributions and voting, consider the following simultaneous-equation vote-contributions model:

$$(1) \quad y_{1t}^* = \gamma_1 E(y_{2t}) + \beta_1' x_{1t} + u_{1t},$$

$$(2) \quad y_{2t} = \gamma_2 E(y_{1t}^*) + \beta_2' x_{2t} + \sigma u_{2t}.$$

Here, y_{1t}^* is a latent variable indicating the propensity of the t th representative to vote for an interest group-specific piece of legislation. The observed counterpart of y_{1t}^* is

$$(3) \quad y_{1t} = \begin{cases} 1, & y_{1t}^* > 0 \\ 0, & y_{1t}^* \leq 0, \end{cases}$$

where $y_{1t} = 1$ for a yes vote; $y_{1t} = 0$ for a no vote; y_{2t} is the net amount of campaign money received by the representative from the interest group, defined as the amount contributed to that representative minus the amount given to his or her electoral opponent(s).

Previous studies generally have treated contributions to electoral opponents as an exogenous variable in an equation explaining gross contributions to the representative or ignored them entirely. Neither approach seems satisfactory. Ideally, the model would have separate equations for contributions to the representative and contributions to his or her opponents. A single net contribution equation is used to keep the model econometrically tractable.¹

A vector of variables, x_{1t} , indicates constituent interests in the motion and the representative's personal ideology. A vector of variables, x_{2t} , measures the legislative power of the representative if elected and the impact of campaign contributions on his or her probability of election. These variables capture the expected returns to a group from a contribution. In addition, γ_1 , γ_2 , and σ are coefficients; β_1 and β_2 are vectors of coefficients; and u_{1t} and u_{2t} are normally distributed random errors with zero means and unit variances.

Equation (1) expresses the propensity to support the legislation as a function of expected net

campaign contributions and exogenous variables. Equation (2) expresses net contributions as a function of expected support for the legislation and exogenous variables. These expected values are obtained by taking expectations of equations (1) and (2), and solving the two-equation system for $E(y_{1t}^*)$ and $E(y_{2t})$.² Expectations are used because neither the representative nor the group can be certain of what the other is doing. The representative does not know what future contributions will be when he or she votes. The group cannot be sure what the representative will do when it contributes prior to the vote.³

Both the legislative motions considered here would have harmed their respective interest groups. If the first linkage between contributions and voting is true (simply buying votes from someone already in office), then $\gamma_1 < 0$. In this case, additional money reduces the likelihood of voting for the motion regardless of constituent interests or the representative's personal preferences. If this linkage is false, $\gamma_1 = 0$. If the second linkage is true (helping to elect someone predisposed to support the group), then $\gamma_2 < 0$. In this case, money is more likely to go to someone whose constituent interests or personal preferences dictate an opposition to the motion. If this linkage is false, $\gamma_2 = 0$.

As a caveat, several interest groups may have a stake in the legislation.⁴ A single group is used here to keep the model clearly focused and econometrically tractable.

Data and Variables

Votes on two amendments to the 1985 farm bill are studied. The first, an anti-sugar motion, would have lowered the loan rate of 18¢ per pound for raw cane sugar in 1985 to 15¢ per pound in 1988 (with the same percentage reduction for beet sugar). It was defeated 147–268 (35%). The second, an anti-dairy motion, would have reduced the milk price support 50¢ per hundredweight per year if government purchases exceeded 5 billion pounds. It would also have eliminated the bill's increases in payment

¹ In this study, counterintuitive results were obtained when gross contributions were used instead of net contributions. Although the impact of voting on contributions was of the expected sign, the impact of contributions on voting was not. The problem may reflect several cases where both a representative and his or her opponent(s) received a lot of money, generating a large value for gross contributions but a small or negative value for net contributions. Many of these representatives voted for the anti-sugar or anti-dairy legislation.

² The solutions are $E(y_{1t}^*) = (\beta_1' x_{1t} + \gamma_1 \beta_2' x_{2t}) / (1 - \gamma_1 \gamma_2)$ and $E(y_{2t}) = (\gamma_2 \beta_1' x_{1t} + \beta_2' x_{2t}) / (1 - \gamma_1 \gamma_2)$. The model's consistency requirement is $\gamma_1 \gamma_2 < 1$.

³ As explained below, both contributions before and after the vote are included in this study. An extended analysis would look at voting and contributions in a dynamic setting.

⁴ Examples are the Sugar Users Group and the Milk Industry Foundation. However, their impact on the 1985 farm bill was definitely limited (Brown, pp. 174–75).

differentials in thirty-three milk marketing order districts. It was defeated 167–247 (40%). Data sources and definitions for all variables are in the appendix.

Contributions during 1983–86 by PACs affiliated with sugar and dairy farmers to representatives of the 99th Congress (1985–86) and their electoral opponents (in 1987 dollars) are used.⁵ Contributions both before and after the votes are used to help avoid prejudging the direction of causality between money and voting. Omitted from the analyses are two representatives serving by 1985 appointment, because they could not have received campaign money in 1984, and the House Speaker. Also omitted are all those who ran for the Senate or state office in 1986, as well as those who retired voluntarily or died between the time of the votes and the 1986 election.

A breakdown of the representatives by voting and net contributions is in tables 1 and 2. Voting and money are clearly associated. The large majority of representatives with positive net contributions voted against the motions. Very few representatives with zero or negative net contributions voted against them. The behavior of those who abstained or voted for these motions in spite of having positive net contributions can be partly understood by looking at table 3. It shows average net contributions for those whose net contributions were nonzero. Those who abstained or voted for the motions received much less on average than those who voted against them. Among those whose net contributions were negative, those who voted no had slightly less spent against them than those who voted yes.

There are too few abstentions to study the determinants of abstaining, so they are excluded from the simultaneous-equation analyses.⁶ Clearly, though, the decision to vote can be as important as the decision about how to vote.

Exogenous variables in the vote equation include the representative's party, his or her "conservatism" (an index from 0 to 1), and the log of one plus group size. Group size is the number of farms in the sugar or dairy standard industrial classification (SIC). District-level data on farm

Table 1. Sugar: Voting and Campaign Contributions

Net Campaign Contributions	Vote			Total
	No	Abstain	Yes	
Positive	224	10	49	283
Zero	12	2	77	91
Negative	6	1	10	17
Total	242	13	136	391

Table 2. Dairy: Voting and Campaign Contributions

Net Campaign Contributions	Vote			Total
	No	Abstain	Yes	
Positive	202	8	76	286
Zero	17	5	60	82
Negative	5	2	16	23
Total	224	15	152	391

Table 3. Average Net Contribution Per Representative

Vote	Net Contributions			
	Sugar		Dairy	
	Negative	Positive	Negative	Positive
No	\$-271	\$2,694	\$-4,224	\$11,642
Abstain	-155*	1,834	-2,074*	5,208
Yes	-320	737	-4,596	3,552

Note: The figures marked with an asterisk should be viewed with caution because they are averages over only 1 or 2 individuals.

organization membership and the number of PAC contributors are not publicly available. Both group size in the representative's district and in his or her state are included. The latter controls for spillover effects from one district to another within a state. Also included is the log of one plus other farms in the district, defined as the total number of farms minus the number in the sugar or dairy SIC. This variable is included to control for vote trading (Abler). Other exogenous variables are the fraction of adults with at least a high school education in the district and the representative's region.⁷

Exogenous variables in the contribution equa-

⁵ Some of the PACs represent more than just farm interests. For example, the American Sugarcane League and Florida Sugarcane League include processors. However, they are predominantly producer organizations (Browne, p. 30).

⁶ A simple option would be to model voting as an ordered probit equation, with an abstention between a yes and a no. However, even this option is precluded by the limited number of abstentions. For sugar, the Hessian was not negative definite at the apparent maximum of the log-likelihood function.

⁷ The log of median family income was also tried. Together, neither income nor education was statistically significant. Separately, education dominated income in terms of asymptotic *t*-ratios.

tion include party, conservatism, the representative's "extremism" (an index from 0 to 1), the log of seniority, and a dummy for incumbency.⁸ Extremism measures deviations from the middle of the road in either direction, so that extreme liberals and extreme conservatives score near 1. More extreme legislators may find the compromises necessary to build successful coalitions less appealing and so may suffer in terms of political influence. Seniority is the reciprocal of the representative's rank within his or her party and is a measure of political power. Incumbency, set equal to 1 if the representative began service prior to November 1984, is a measure of the impact of money on the probability of election. Incumbents have well-known electoral advantages over challengers.

Net contributions are measured as $\delta(m) \log(1 + |m|)$, where m is the net amount of campaign money received and $\delta(\cdot)$ is the sign function. Log transformations here and on the group size variables mitigate against outliers.

Results

Maximum likelihood estimates of the simultaneous-equation systems are in table 4. The results for sugar and dairy tell the same story with respect to the linkages between voting and contributions. The expected propensity to vote for an anti-group motion has a negative and statistically significant effect on group contributions. For each group, money apparently goes to people who like its programs. However, expected net contributions have a negative and statistically insignificant impact on voting. Neither sugar nor dairy PACs seem to be able to buy votes directly from representatives. Virtually the entire association between money and voting appears to operate through the election of those predisposed to support sugar or dairy programs.

These results on the direction of causality between money and voting are consistent with Chappell. Looking at several issues, including dairy price supports in 1975, he found little effect of contributions on voting after accounting for correlated errors in the vote and contribution equations. The results are also consistent with

Peltzman, who found that ideological and party affiliation differences among senators were largely explained by characteristics of campaign contributors and constituents as a whole. Contrast the results with single-equation models, which typically show that money has a large effect on voting (e.g., Welch).⁹

Incumbents start out with large advantages over challengers, as is well known, and the results suggest that they are augmented by sugar and dairy PACs. Interestingly, seniority is not an important factor in contribution decisions. Those with more seniority have more power and can exercise some control over other members, but this may give them a greater ability to ignore PACs. Although extremism has the expected sign, it is not statistically significant.

There is weak evidence that conservatives receive more money, which may result from their political clout during the first half of the 1980s. Party does not seem to influence contribution decisions. Democrats had firm control of the House in 1985, but this may have been offset by the Republicans' greater access to President Reagan. The results for conservatism and party suggest that sugar and dairy contributions can depend on the larger political environment as well as the specifics of a representative and his or her constituents.

In the vote equation, spillover effects from one district to another within a state appear important for sugar but not dairy. Sugar growers received support from other farms, whereas dairy farmers did not. Education is positively associated with support for the anti-sugar and anti-dairy motions. This makes sense because the more educated have higher incomes on average and likely are more knowledgeable about the impacts of sugar and dairy programs.

Conclusions

In this article, I have explored the determinants of campaign contributions by sugar and dairy PACs and their role in voting on sugar and dairy legislation in the U.S. House of Representatives. Voting on anti-sugar and anti-dairy amendments to the 1985 farm bill and campaign contributions in 1983–86 by PACs affiliated with sugar and dairy farmers were studied. A strong

⁸ Membership on the House Agriculture Committee and the sugar or dairy subcommittee were also tried. However, there are too few members on each subcommittee or even the committee to use these variables. For both sugar and dairy, the Hessian was not negative definite at the apparent maximum of the log-likelihood function when either variable was included.

⁹ Single-equation probit estimates here of the impact of net contributions on voting yield coefficients (absolute t -ratios) of -0.22 (7.8) for sugar and -0.11 (6.3) for dairy.

Table 4. Simultaneous Equation Results

Variable	Sugar		Dairy	
	Vote	Contributions	Vote	Contributions
Expected propensity to vote yes		-1.02* (3.7)		-2.15* (3.6)
Expected net contributions	-0.11 (1.1)		-0.004 (0.0)	
Party (Dem. = 0, Rep. = 1)	0.36 (1.0)	-0.52 (0.7)	0.72 (1.4)	-1.19 (1.1)

Note: Absolute values of asymptotic t -ratios are in parentheses. An asterisk denotes a t -ratio at least 2 in absolute value. Maximum likelihood estimates (t -ratios) for σ are 3.11 (27.3) for sugar and 4.31 (27.3) for dairy, compared with sample standard deviations for the net contributions variable of 3.88 and 4.92.

association between money and voting was found. However, the results show that sugar and dairy farmers were unable to use campaign contributions to buy votes from representatives who might otherwise vote against them. The association appears to result almost entirely from the role contributions play in helping to elect people predisposed to support sugar and dairy programs.

The major policy implication to come out of

this study concerns the impact of a limit or ban on PAC contributions, which many have proposed. Given the inability of sugar and dairy PACs to buy votes directly, the results imply that the short-run impact on sugar and dairy policy would be quite small. In the long run, however, representatives not so supportive of sugar and dairy programs could replace current ones as PAC money ceased to be such an important

factor in election campaigns. Thus, the long-run impact could be substantial.

- Party.** Democrat = 0, Republican = 1. Source: *Congressional Quarterly Almanac*, 1985.
- Conservatism.** Defined as YES/(YES + NO). YES (NO) is the number of conservative coalition roll calls on which the representative cast a roll call vote in agreement (disagreement) with the position of the conservative coalition in the 99th Congress. The conservative coalition is a voting alliance of Republicans and Southern Democrats against Northern Democrats. A conservative coalition roll call is any roll call on which the majority of voting Republicans and the majority of voting Southern Democrats cast a roll call vote opposite to that cast by the majority of voting Northern Democrats. Source: *Congressional Quarterly Almanac*, 1985 and 1986.
- Extremism.** Defined as $2|C - 0.5|$, where C is the value of the conservatism index above.
- Seniority.** The reciprocal of the representative's rank within his or her party. Source: *Congressional Quarterly Almanac*, 1985.
- Incumbent.** Equals 0 if the representative began service in November 1934 or later; equals 1 otherwise. Source: *Congressional Quarterly Almanac*, 1985.
- Farm Groups.** The number of farms in an appropriate standard industrial classification (SIC), 1987. The SICs used are sugar (0133) and dairy (024). Congressional district data on farm numbers were constructed from county data in the 1987 Census of Agriculture. For sugar, where county data are unavailable, the following approximation is used: $SIC_{ij} = (TOTAL_{ij}/TOTAL_j)SIC_j$, where i is state and j is county. $TOTAL$ is the total number of farms producing the commodity, while SIC is the number in the commodity's SIC. The number of other farms is the total number of farms of all types minus the number in the sugar or dairy SIC.

Appendix

Data Sources and Variable Definitions

Vote. Each of the following actions is counted: a roll call vote; a specific (but not general) paired vote; a publicly announced position; and a response to a Congressional Quarterly poll. The CQ House vote numbers are 289 (sugar)

The county data were aggregated to congressional district data using maps of congressional districts and tables listing the congressional districts(s) in each county in the U.S. from the *Congressional District Atlas*, 99th Congress. For a county with more than one district in it, the totals for that county were apportioned among districts in accordance with a rough guess of the percentage of the county's rural area in each district.

Education. Fraction of persons aged twenty-five and over who have completed high school, 1980. sources: *1980 Census of Population and Housing: Congressional Districts of the 98th Congress*; and *1980 Census of Population and Housing: Congressional Districts of the 99th Congress*.

Regional Dummies. The Census Bureau regions are used. The control region is New England.

The Aggregate Effects of Risk in the Agricultural Sector

Jack Meyer and Lindon J. Robison

The theory of the firm facing a random output price is extended to include industry equilibrium conditions in a way particularly important for agriculture. Land prices adjust to maintain industry equilibrium. The comparative statics and the effects of policy for the firm are significantly altered. The main finding is that risk and other parameter changes are capitalized into the price of land and yield wealth or income effects rather than substitution effects. This often simplifies the analysis.

Key words: competitive firm, land prices, mean-variance, risk.

Empirical research has demonstrated that adjustments in land prices are an important equilibrating mechanism for the agricultural sector. Public policies and farm programs are known to affect land prices (e.g., Vantresse, Reed, and Skees). Changes in the riskiness or level of returns to agricultural production are also reflected in land prices (Robison, Lins, and VenKataraman). Developing a single aggregate model under risk which displays the linkages between risk, return, and land prices is our main task in this paper. The purpose is to understand better the effects of public policies which alter the returns and risk faced by the agricultural producer.

This study also adds to the vast literature concerning a competitive firm facing a random output price. Equilibrium conditions are obtained for such a firm operating in a competitive industry where an input's price adjusts to maintain industry equilibrium. The findings complement the recent work of Appelbaum and Katz, who analyze competitive firms facing output price risk when operating in a constant cost industry.

The competitive agricultural firm modeled here uses land and other inputs in producing a product whose price is random. The price of land is assumed to rise or fall to maintain equilibrium in the industry. Two approaches, an asset pricing model and explicit supply and demand re-

lationships for land, are used to determine equilibrium land prices.

The comparative statics for the individual firm in this model are quite different from those obtained by Sandmo and others who ignore industry equilibrium considerations. This paper's results also differ from those of Appelbaum and Katz, who assume a different industry equilibrating mechanism.

The paper is organized as follows. First, the literature concerning the competitive firm in a competitive industry is reviewed, and a simple model of a competitive firm facing a random output price and using land as an input is presented. The next section develops conditions for equilibrium in a competitive industry when land is in fixed supply and its price adjusts to maintain equilibrium in the industry. Then, the model is expanded to reflect more adequately the conditions in the agricultural sector. Finally, a general policy example highlights the differences between comparative static results in this model and those obtained by others.

The Competitive Firm in a Competitive Industry

A large literature concerning the competitive firm operating in a competitive industry exists. The starting point is a model where the firm chooses output level x to maximize profit, π , where $\pi = p \cdot x - c(x)$. In this model, p represents the output price and $c(x)$ is the cost function.

Without randomness, the industry is assumed to be in equilibrium when the firm earns zero

Jack Meyer and Lindon J. Robison are professors of economics and agricultural economics, respectively, at Michigan State University.

Funding was provided jointly by the Michigan Agricultural Experiment Station and Economic Research Service, U.S. Department of Agriculture under research agreement number 58-3J23-4-00276.

profit. For the constant cost industry case, $c(x)$ is exogenous to both the firm and the industry and only output price can adjust to attain zero profit. The standard assumptions are that p depends on the industry output level Q and that entry or exit occurs until Q implies zero profit for each firm, i.e., $p(Q) = c(x)/x$.

Sandmo extends the competitive firm model to the case where output price is a random variable and expected utility of profit is maximized. The effects of shifting various parameters, including the mean and the riskiness of the output price, are also determined. Comparative statics in this model differ from the certainty case; moreover, these differences have received much attention in the agricultural economics as well as the economics literature.

Recently, Appelbaum and Katz note that Sandmo fails to consider equilibrium in the competitive industry. That is, how the individual firm reacts to changes in certain parameters is calculated without determining whether or not those parameter changes are consistent with equilibrium in the competitive industry.

Appelbaum and Katz add to Sandmo's analysis by including an output price which is a random variable whose mean depends on industry output level. They assume that output price is given by $p(Q) + \epsilon$, where ϵ is random with a zero mean, and $p(Q)$ is a nonrandom term giving the mean output price as a decreasing function of industry output level. Costs are assumed exogenous to the firm and to the industry.

Industry equilibrium is attained when no firm desires to enter or exit the industry. Because profit is a random variable, it cannot be set equal to zero. Instead, Appelbaum and Katz assume that firms can attain a reservation level of expected utility in other activities and choose to enter or leave this industry if the expected utility from profit exceeds or falls short of this reservation level.

This industry equilibrium requirement implies that the mean output price depends on all other parameters in the model, a link which does not exist in the Sandmo formulation. Thus, shifts in those parameters have effects in addition to those determined by Sandmo. Consequently, Appelbaum and Katz find the comparative statics for the firm are significantly altered when industry equilibrium conditions are considered.

For certain industries a second mechanism for adjusting to industry equilibrium exists. Adjustments in input prices can alter a firm's cost function, thus altering the firm's desire to enter

or exit the industry.¹ This mechanism is particularly relevant in agriculture because adjustments in land prices, and hence costs of production, alter the profitability of firms in the industry.

When microeconomists wish to focus exclusively on this second mechanism for attaining industry equilibrium, a simple model with only one input in fixed supply is often considered. Furthermore, only the price of this input is assumed to adjust to induce entry or exit from the industry.

Formally, in this one input model, profit is given by $\pi = p \cdot L - \phi \cdot M \cdot L$, where L is the input level chosen by the firm. Constant returns to scale is assumed and one unit of input produces one unit of output.² As is usual under the constant cost assumption, firm size is indeterminate. Because land is a durable, its cost is written as a per period cost $\phi \cdot M$, where ϕ is the risk-free interest rate and M is the durable's price.

The competitive firm treats input and output prices as exogenous variables. For the industry however, the input price adjusts to maintain industry equilibrium. Because input L is available in fixed supply, its price serves as a rationing mechanism. Without randomness, industry equilibrium is again characterized by the zero profit condition. This implies the standard capitalization formula $M = p/\phi$ as the equilibrium price for the durable input. The return per period for the durable is capitalized using the risk-free discount rate.

This model of a competitive firm can be extended to the random output price case. Profit is given by $\pi = p \cdot L - \phi \cdot M \cdot L$ as before, but now p is a random variable. The firm is assumed to choose L to maximize expected utility of profit. If strict risk aversion is assumed, even with constant returns to scale, a finite solution for L obtains and firm size is determinate.

Output price p is the only source of randomness in this model, and profit is a positive linear transformation of p . Thus, all potential profit distributions are location and scale transformations of the distribution of output price. This

¹ When input prices increase to reduce profits earned by firms in an industry, this is often referred to as the increasing cost industry case.

² The case of nonconstant returns to scale can also be considered. The profit expression becomes $\pi = p \cdot f(L) - \phi \cdot M \cdot L$, where $f(L)$ is the production function. $f(L)$ must be such that firms are neither infinitely small nor large, and the zero profit condition requires that $M = p \cdot f(L)/\phi \cdot L$.

property allows the optimal choice of L and much of the comparative static analysis to be conducted in a mean-standard deviation (MS) framework without violating the expected utility maximization assumption or imposing other special assumptions.³

The MS formulation of the decision model with $\pi = p \cdot L - \phi \cdot M \cdot L$ has the competitive firm choosing L to maximize $V(\sigma, \mu)$, where mean $\mu = \mu_p \cdot L - \phi \cdot M \cdot L$ and standard deviation $\sigma = \sigma_p \cdot L$. The notation μ_p and σ_p represent the mean and standard deviation of output price, respectively. Solving for L in the expression for σ and substituting into the expression for μ reduces the pair of constraints to the linear restriction given as equation (1). The firm's choice of L is a selection of some point on this straight line opportunity set in (σ, μ) space.

$$(1) \quad \mu = (\mu_p - \phi \cdot M) \cdot \sigma / \sigma_p.$$

Notice that the firm's opportunities depend on the four parameters, μ_p , σ_p , ϕ , and M .

As in the model without randomness, industry equilibrium considerations imply that the price of the input L adjusts to attain the appropriate profit level. Because profit is random, the equilibrium land price is more difficult to define. The next section first uses an asset-pricing model to resolve the issue and then develop an alternate approach involving supply and demand equations for land.

Input Price Adjustment and Industry Equilibrium

The input L is an asset which generates a random rate of return p/M in each time period. The level of the asset price, M , which implies an equilibrium random rate of return, must be resolved. The random return to L is similar to the return from holding one unit of a financial asset, such as a share of stock. The capital asset pricing model (CAPM) suggests that the price of the asset or input adjusts until its mean rate of return is equal to the risk-free rate of return plus a risk adjustment factor. This factor depends on the market compensation for risk, $[(\mu_m - \phi)/\sigma_m]$, the diversification characteristics of the asset, ρ , and the riskiness of the return, (σ_p/M) . In these expressions, ϕ is the risk-free rate of return, μ_m

and σ_m are the mean and standard deviation of the rate of return on the market portfolio, and ρ is the correlation coefficient between the rate of return on this asset and the rate of return on the market portfolio.

Formally applying the CAPM to the pricing of the input L requires that the mean return per dollar satisfies⁴

$$(2) \quad \begin{aligned} \mu_p/M &= \phi + [(\mu_m - \phi)/\sigma_m] \\ &\cdot \rho \cdot (\sigma_p/M) = \phi + \eta \cdot (\sigma_p/M). \end{aligned}$$

For notational convenience, η represents both the market compensation for risk and the asset's diversification possibilities.⁵ The η term will be treated as fixed throughout this analysis.

The CAPM assumes that the asset is part of a maximally diversified portfolio called the market portfolio. Levy has demonstrated that a pricing formula exactly like (2) holds even with a limited ability to diversify. The coefficient η still represents both the market price of risk and the diversification possibilities of the asset. Now, however, the $[(\mu_m - \phi)/\sigma_m]$ and ρ terms are calculated with respect to a less well-diversified portfolio than the market portfolio. It makes no difference in this analysis whether (2) results from CAPM or Levy's argument. Thus, the interpretation of η is left purposely ambiguous.⁶

The equilibrium value for M which pricing equation (2) implies is given by

$$(3) \quad M = (\mu_p - \eta \cdot \sigma_p) / \phi = \mu_p / \phi - \eta \cdot \sigma_p / \phi.$$

As in the example without risk, the industry equilibrium condition provides an additional link among the parameters in the model and quite different comparative statics result.

Before exploring the implications of this additional equilibrium condition, an alternate approach not using CAPM is presented. This second method of modeling the equilibrium price for land specifies a particular functional form for each firm's preferences in order to calculate an explicit demand function for L . The linear mean-variance utility function is assumed. That is, the i th firm is assumed to choose L_i to maximize $\mu_i - (\lambda_i/2)\sigma_i^2$, where $\mu_i = \mu_p \cdot L_i - \phi \cdot M \cdot L_i$ and $\sigma_i = \sigma_p \cdot L_i$. The parameter λ_i represents the risk aversion measure of the firm and

⁴ Since one unit of output is produced per unit of input, μ_p and σ_p are also the mean and standard deviation of return per unit of input.

⁵ In standard CAPM notation, the η term is not equal to the traditional CAPM beta (β) but is related to it in the following way: $\eta = (\mu_m - \phi) \cdot \beta \cdot \sigma_p / \sigma_p$.

⁶ Barry has treated the pricing of agricultural land using both CAPM and Levy's pricing argument.

³ Sinn and Meyer describe the implications of this location and scale property. Meyer and Robison use it to analyze the hedging behavior of the competitive firm.

is assumed positive. Choosing L to maximize this function leads to

$$(4) \quad (\mu_p - \phi \cdot M) - \lambda_i \cdot \sigma_p^2 \cdot L_i = 0$$

as the first-order condition, with the second-order condition satisfied since λ_i is positive.

Solving for the optimal choice of L_i , one obtains

$$(5) \quad L_i = (\mu_p - \phi \cdot M) / (\lambda_i \cdot \sigma_p^2).$$

Thus, the individual producer's demand for L depends on all of the parameters in the model: the mean and variance of output price, the risk-free rate of return, the input price, and the producer's risk aversion level. Only this latter term is firm specific.

The demand functions for the durable input can be easily added across n firms. Doing so, one obtains

$$(6) \quad L_D = ((\mu_p - \phi \cdot M) / \sigma_p^2) (1/\lambda_1 + \dots + 1/\lambda_n)$$

as the aggregate demand function for the n producers.

To find the equilibrium price for L , this demand function is set equal to the given supply L_o . Solving for M one obtains

$$(7) \quad M = (\mu_p / \phi) - (L_o \cdot \sigma_p^2) / (\phi \cdot (1/\lambda_1 + \dots + 1/\lambda_n)).$$

The form of this pricing equation is similar to equation (3) based on the CAPM argument. That is, in equilibrium, the price of L equals a capitalization of the mean return, plus a term which discounts for the riskiness of the production activity and the diversification possibilities of spreading the risk across the n producers. For this supply and demand case, the equivalent of η is the term $(L_o \cdot \sigma_p^2) / (1/\lambda_1 + \dots + 1/\lambda_n)$. This expression represents the diversification possibilities of distributing $L_o \cdot \sigma_p^2$ units of risk across n different individuals with risk aversion measures λ_i . As the agricultural producer's risk aversion goes to zero, the premium caused by the riskiness of profits also goes to zero.

Firm Behavior Constrained by Industry Equilibrium

Comparative static analysis in the model of the firm is significantly altered when industry equilibrium is considered. Recall that μ_p , σ_p , ϕ , and M together define the firm's opportunities in

equation (1) and, hence, affect its choices. Under industry equilibrium, these four parameters are linked by an additional equation, either (3) or (7), depending on whether the asset-pricing or supply and demand argument is employed. Interestingly, this additional equation actually simplifies the analysis.

For instance, when the value for M given by (3) is substituted into (1), the constraint the firm faces becomes $\mu = \eta \cdot \sigma$. Thus, only the market price of risk and the diversification parameter affect the firm's opportunities. Changing the mean or riskiness of output price is offset by the resulting adjustments in M so that the firm's opportunity set remains unchanged.

Similar simplification occurs when the equilibrium value for M arises from supply and demand analysis. In this case, (7) is substituted into the first-order condition for the firm, (4). This yields $L_o / (1/\lambda_1 + \dots + 1/\lambda_n) - \lambda_i \cdot L_i = 0$. The firm's choice of L_i no longer depends on the mean or variance of output price but only on the available supply of land and the firm's risk-aversion level relative to others in the industry.

This model of the competitive firm is adequate to discuss the impact of industry equilibrium on the price of land. It is not, however, sufficiently well developed to consider the agricultural policy implications of this aggregate risk model. Thus, the model is augmented with several other parameters to enrich the analysis.

First, the initial wealth of the firm is assumed nonzero and held as cash and land. Thus, parameter changes affect the agricultural firm's wealth through their impact on land prices.

Let $C_o + M \cdot \bar{L}$ be the firm's initial wealth, where C_o represents the cash portion, and $M \cdot \bar{L}$ is the land wealth. Producers own different amounts of land but can use quantities of land which differ from the amount owned. With this change one can distinguish between the effects of various programs on producers who rent versus those who own their land. Because nearly three-fourths of the agricultural sector's assets consists of land, this change in the model is particularly relevant.

The second change in the model is to introduce other inputs in the production of output. Even if the land quantity is fixed, industry output can expand or contract by altering other inputs. Formally, output level is assumed to be given by $L \cdot f(s)$, where s represents another input or a vector of inputs. These inputs are measured per acre of land. As before, this production function represents a constant returns-to-scale

P 7688

process with output per acre depending on s .⁷ The function $f(s)$ is increasing and concave in its arguments.

The producer's objective is to choose L and s to maximize expected utility from terminal wealth W given by

$$(8) \quad W = (1 + \phi)(C_o + M \cdot \tilde{L}) + (p \cdot f(s) - \phi \cdot M - p_s \cdot s) \tilde{L},$$

where p_s is the vector of prices for inputs s . The producer takes all prices as parameters outside its control. This wealth function is linear in the random variable, and hence MS analysis is appropriate.

In the MS framework, the producer chooses L to maximize $V(\sigma, \mu)$, where $\mu = (1 + \phi)(C_o + M \cdot \tilde{L}) + (\mu_p \cdot f(s) - \phi \cdot M - p_s \cdot s)L$ and $\sigma = \sigma_p \cdot f(s) \cdot L$. Again, one can solve for L in the second restriction and substitute into the first to define a linear opportunity set in (σ, μ) space.

$$(9) \quad \mu = (1 + \phi)(C_o + M \cdot \tilde{L}) + (\mu_p \cdot f(s) - \phi \cdot M - p_s \cdot s)\sigma/(\sigma_p \cdot f(s)).$$

All model parameters affect the producer's opportunity set and many impact the slope as well as the intercept. Equation (9) is the producer's constraint if industry equilibrium considerations are ignored. Under risk aversion, $V(\sigma, \mu)$ is known to be quasi-concave and the second-order conditions for the maximization are satisfied.

The level of s only affects the slope of (9). Thus, all risk-averse producers choose s to maximize this slope independent of their risk attitudes. On the other hand, producers choose different levels of L depending on their risk-taking characteristics. Each value for L is represented by a particular point on the linear opportunity set in (σ, μ) space.

The level of s which maximizes the slope of (9) is defined by $(\phi \cdot M + p_s \cdot s)/f(s) = p_s/f'(s)$. The left and right sides of this equality are the producer's average cost and marginal cost per acre, respectively. Thus, all producers choose to operate where the average cost of production is at its minimum. However, changes in various parameters can affect this level of output per acre. Specifically, changes which induce increases in the price of land will cause the output per acre to rise.

As in the simple model, other input prices and output prices are assumed exogenous to the in-

dustry. Only the price of land adjusts to maintain industry equilibrium. The resulting equilibrium price for land is given by an equation similar to (3) or (7) found earlier. The CAPM pricing argument applied to this more general model requires that the rate of return to land satisfy

$$(10) \quad (\mu_p \cdot f(s) - p_s \cdot s)/M = \phi + \eta \cdot \sigma_p \cdot f(s)/M.$$

The rate of return to land is the value of output per acre exclusive of other input costs divided by the price of land. The mean, standard deviation and correlation are calculated for this term. Solving equation (10) for M leads to a land-pricing equation.

$$(11) \quad M = (\mu_p \cdot f(s) - p_s \cdot s - \eta \cdot \sigma_p \cdot f(s))/\phi.$$

Similarly if one assumes the explicit linear mean-variance preference function and requires that the demand for land is equal to a fixed supply, the price of land satisfies

$$(12) \quad M = ((\mu_p \cdot f(s) - p_s \cdot s)/\phi) - (L_o \cdot (\sigma_p \cdot f(s))^2)/(\phi \cdot (1/\lambda_1 + \dots + 1/\lambda_n)).$$

To capture the industry equilibrium condition arising under the CAPM argument, land-pricing equation (11) is substituted into the firm's linear constraint (9). The opportunity set for the firm then is

$$(13) \quad \mu = (1 + \phi)(C_o + (\mu_p \cdot f(s) - p_s \cdot s - \eta \cdot \sigma_p \cdot f(s)) \cdot \tilde{L}/\phi) + \eta \cdot \sigma.$$

Changes in all parameters other than η only shift the intercept of this linear constraint, their effect is equivalent to a change in initial wealth. For this simple model, when agriculture is in competitive equilibrium, the effects of changing the mean or riskiness of output price are capitalized into the price of land. Parameter changes have no effect if $\tilde{L} = 0$, i.e., if the producer is not a land owner. Hence, the impact of these changes depends on the producer's land ownership position.

Equation (13) indicates that shifting any parameter except τ is represented by a parallel shift in the opportunity set in (σ, μ) space. The effect of a parallel shift in the opportunity set depends on the producer's risk-aversion characteristics (Meyer and Robison). If the producer is constant absolute risk averse, no change in the optimal L occurs, while acreage increases (declines) under decreasing (increasing) absolute risk aversion.

If the supply and demand model for land is

⁷ If constant returns to scale is not assumed, the analysis becomes considerably more complicated.

used to determine an equilibrium price for land, the analysis is less interesting because wealth effects in the linear mean variance model do not affect the producer's choice of L when λ_i is treated as a constant. It is possible, however, to treat λ_i as a variable in order to analyze this case more fully (Robison and Barry). The optimal level of s and L are defined by the equations:

$$\mu_p \cdot f'(s) - p_s - \lambda_i \cdot \sigma_p^2 \cdot f(s) \cdot f'(s) \cdot L_i = 0 \text{ and} \\ L_o / (1/\lambda_1 + \dots + 1/\lambda_n) - \lambda_i \cdot L_i = 0.$$

A Policy Application

The federal government provides many opportunities to alter the mean and/or riskiness of output price through participation in government-sponsored programs (Gardner, Gardner et al., Fleisher). A general example of these programs is used here to illustrate how policy evaluation could change when industry equilibrium is considered.

Suppose government intervention in commodity markets attempts to maintain or increase the mean price while reducing its variability and that program participants are required to idle $(1 - \alpha)$ percent of the land. That is, $\mu_p = \mu_p(G)$ and $\sigma_p = \sigma_p(G)$, where G is an exogenously determined level of government intervention. If the idled land produces nothing of value, then the opportunity cost to the producer of using land increases, and is $\phi \cdot M/\alpha$ rather than $\phi \cdot M$.

When these changes are introduced into (9), equation (14) results. This is the product's constraint ignoring industry equilibrium conditions. The G and α parameters alter the slope but not the intercept of this line.

$$(14) \quad \mu = (1 + \phi)(C_o + M \cdot \bar{L}) + (\mu_p(G) \cdot f(s) - \phi \cdot M/\alpha - p_s \cdot s) \sigma / (\sigma_p(G) \cdot f(s)).$$

Analysis of the firm's response to changes in G or α involve income and substitution effects, and the results are often ambiguous. Also, because \bar{L} only enters the intercept term, the impact of changes in G or α do not depend on the extent to which producers own their land.

When industry equilibrium is considered, the price for land must be adjusted to incorporate these government effects. The CAPM argument requires that the net return per unit of land satisfy

$$(15) \quad \alpha \cdot (\mu_p(G) \cdot f(s) - p_s \cdot s) / M \\ = \phi + \eta \cdot \alpha \cdot \sigma_p(G) \cdot f(s) / M,$$

where the return per acre is adjusted to account for the $1 - \alpha$ percent which is idled. Solving for M yields

$$(16) \quad M = \alpha \cdot (\mu_p(G) \cdot f(s) - p_s \cdot s - \eta \cdot \sigma_p(G) \cdot f(s)) / \phi.$$

When this value for M is substituted into the producer's constraint, (14), the resulting opportunity set displays far different sensitivities to government action. The new opportunity set is

$$(17) \quad \mu = (1 + \phi)(C_o + \alpha \cdot (\mu_p(G) \cdot f(s) - p_s \cdot s - \eta \cdot \sigma_p(G) \cdot f(s)) \cdot \bar{L} / \phi) + \eta \cdot \sigma.$$

Now the government's actions only shift the intercept and do not affect the slope of the linear constraint. The effect of these changes can generally be determined on the basis of an assumption concerning the producer's absolute risk-aversion measure.

The effect of the government's choice of G or α is proportional to the value for \bar{L} . The opportunity set and welfare of producers who only rent land, $\bar{L} = 0$, is not affected by the government's choice of G and α . These producers do make different decisions concerning the level of other inputs since the optimal s depends on M , but their overall opportunities to earn profits are not affected by the government actions. For instance, if μ_p is increased through a support price, land prices rise so that renters find the random rate of return to agricultural production no different than before.

When the producer owns some or all of the land which is used, $\bar{L} > 0$, changes in G or α alter the producer's opportunity set and welfare by changing initial wealth. Changes which increase (decrease) M make the producer better (worse) off. These welfare changes, however, are the result of the gains to these individuals as land owners and not from their agricultural production activities.

Conclusions

Of course this model abstracts from the realities of the situation. Prices other than land prices are likely to adjust in order to maintain industry equilibrium. Nonetheless, this paper extends the theory of the firm facing a random output price to include industry equilibrium conditions in a way particularly important for agriculture. It complements the work of Appelbaum and Katz, who analyze the constant cost industry.

The comparative statics for the firm are significantly altered when industry equilibrium is

considered. For the agricultural firm, the effects of policies which alter the mean or riskiness of output price are different than when industry equilibrium conditions are ignored. The main finding is that risk and other parameter changes are capitalized into the price of land and yield wealth or income effects rather than substitution effects. This greatly alters and often simplifies the comparative statics in the model of the competitive firm.

Application of Computer Graphics to Undergraduate Instruction in Agricultural Economics

David L. Debertin and Larry D. Jones

This article outlines are experience in building a freshman-level course in agricultural economics employing computer graphics imaging. Lecture material is displayed with a computer connected to a large-screen projector producing high-resolution graphics. The complete course consists of approximately 1,200 computer-generated text, chart, or graphics images. An evaluation of the new method was conducted. Results indicate that most students prefer lectures that employ computer graphics to those that use a chalkboard or an overhead projector. Evidence supports the hypothesis that students perform better on exams when the innovations described in this paper are adopted.

Key words: computer graphics, teaching technology, undergraduate instruction.

It is now feasible to develop and use computer graphics and imaging technologies to teach an entire undergraduate course in agricultural economics. Computer graphics has been used in the past for data analysis (Bay and Schoney; Debertin, Pagoulatos, and Bradford), for the analysis of functions used in agricultural economics research (Debertin, Pagoulatos, and Bradford), and to supplement textbook presentations (Debertin 1985 and 1986). Harris employed computer graphics as an instructional aid in teaching a futures trading course. Computers, sometimes connected to television monitors, have been used in undergraduate agricultural economics courses, particularly in portions of courses requiring spreadsheets, linear programming models, simulators, or other computerized decision aids (Bentley, Hudson et al., Litzenberg, Osburn et al.).

Agricultural economists are convinced of the need for (a) frequent updating of undergraduate curricula (Coffey, Erven, Dobson, Kropp 1973a);

(b) competency-based curricula development (Beck et al., Mather et al.); (c) incorporating computer skills into revamped curricula (Manderscheid, p. 744); and (d) new technologies using microcomputers to improve educational delivery (Harris, Hudson et al., Litzenberg). Discussion in our journals suggests that new teaching technologies, particularly those that use microcomputers, have had greater impacts on adult than on undergraduate education (Brown, Diesslin, Holt, Hughes). Fuller argues (p. 980) that "we can and should be using computers . . . as an integral part of our educational program." Hudson et al. (p. 177) suggest that "continuing advances in technology offer a growing variety of educational uses of the microcomputer not previously considered."

Extension educators, not undergraduate teachers, frequently have been the earliest to adopt the new information-delivery technologies employing computers. Recently, Wetzstein (p. 63) even argued that the new technologies for teaching basic economics, such as television and computers in instruction, "stifle students' imaginations, contribute to a dependent learning style, and fail to stimulate interest in the subject matter." Our experiences with new teaching technologies employing computers and color projection monitors suggest otherwise; these new technologies have helped students better learn principles of basic economics applied to agriculture than when conventional teaching methods were employed.

David L. Debertin is a professor of agricultural economics, and Larry D. Jones is a professor and chair, Department of Agricultural Economics, University of Kentucky.

The investigation reported in this paper, no. 90-1-106, is in connection with a project of the Kentucky Agricultural Experiment Station and is published with the approval of the director.

Debertin was responsible for developing all of the computer graphics images comprising the course and teaches the course in the fall semester; Jones teaches the course in the spring semester, using the computer graphics images and study guide.

Appreciation is extended to Joe T. Davis for helpful comments on an earlier draft of this manuscript.

This paper outlines experiences at the University of Kentucky in building a freshman-level course in agricultural economics employing microcomputer graphics imaging as the basis for every lecture and using the method to teach a class of undergraduate students. As part of the new method, other teaching innovations were also developed, and these are also described in the discussion that follows. Evaluations of student reactions to these innovations and their effect on student performance on examinations were conducted, and the results are presented.

The Methods

All of the notes, charts and diagrams used in the course were developed using computer graphics software.¹ Throughout the semester, lecture material was displayed to students using a computer connected to a large-screen projector capable of producing text and high-resolution (EGA/VGA) graphics. The complete course consists of approximately 1,200 computer-generated text, chart, or graphics images. Many of the graphics images are built sequentially, one line at a time, and were designed to mimic the manner and speed which the instructor would have used in a chalkboard presentation or a presentation using color pens, transparencies, and an overhead projector. The computer graphics images, however, are in full color, more accurately drawn, and easier to interpret than hand-drawn graphs.

Additional elements are also important in the new teaching method. The text and graphics images displayed on-screen are supplemented by a study guide containing the charts, graphs, and other key lecture materials for the course.² The study guide closely follows the computer-generated slide shows. Gaps are built into the study guide that the instructor "fills in" during the lecture. The study guide is unique because it also functions as the student's notebook. A series of

six comprehensive worksheets containing questions and exercises and based on the study guide and lecture presentation cover every major topic. These worksheets force students to review notes taken during class and the related material in the study guide. Two supplemental computerized slide shows are available to students for individualized instruction. These slide shows provide additional help in completing the exercises dealing with production and cost and are available to students on computers in the undergraduate computer lab. All of these elements and methods are closely interrelated. For example, the study guide is based on the computer-generated lecture images, worksheets are based primarily on study guide and lecture presentations, and the supplemental slide shows are based on the two most difficult worksheets. Examinations and quizzes cover the entire course but place particular emphasis on worksheet material. We evaluated the effectiveness of each of these elements.

The Course

Because of the variety of material covered, the introductory agricultural economics course provided a nearly ideal vehicle for testing the potential and limitations of the approach. The course (called GEN 1C1) consists of three sections. The first section develops an awareness of basic issues confronting U.S. and Kentucky agriculture. (Most of the students enrolled in the course come from rural nonfarm backgrounds or from "part-time" and "hobby" farms, although most are enrolled in the college of agriculture.) Included are issues related to declining farm numbers, changing consumption patterns for agricultural commodities grown in Kentucky, and the importance of various enterprises to farm income in Kentucky. Considerable use is made of charts developed for the course that are similar to those found in the USDA Chartbook, but an emphasis is placed on issues and data important to Kentucky.

The second section introduces basic principles of microeconomic theory using case examples from agriculture. Figures 1 and 2 provide some illustrative examples of the content and level in the microtheory section and illustrate the sequential building of diagrams one line at a time. One of the key elements involves drawing sequences that mimic the manner in which an instructor might draw on a chalkboard or overhead transparency, but with greater clar-

¹ The course was constructed in its entirety using Harvard Graphics, currently used in many agricultural economics departments primarily for research and extension applications drawing technical graphs. A computer disk (for use on an IBM compatible computer with EGA or VGA graphics) containing examples of drawings and lessons developed for the course is available at no charge by contacting either of the authors.

² The study guide contains all of the diagrams and lecture notes displayed on-screen. Some of the graphs that are constructed in several steps and the text material that is presented on-screen one point at a time is included only in final form. The study guide has been duplicated by and sold to students through the campus bookstores. A new version incorporating worksheets and a glossary of terms used in each lesson is available nationwide (Debertin 1990).

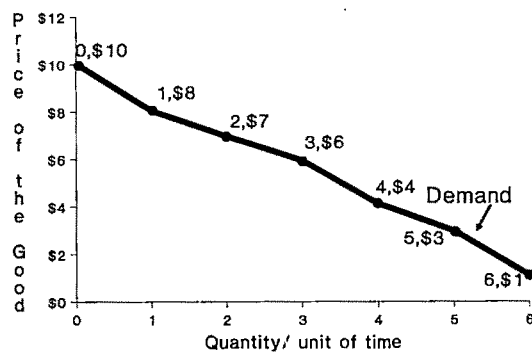

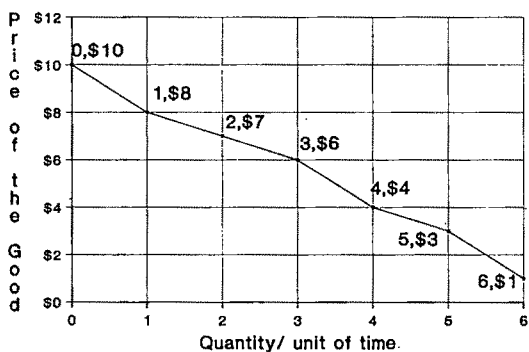

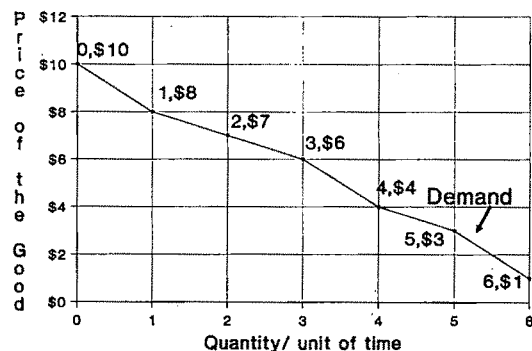

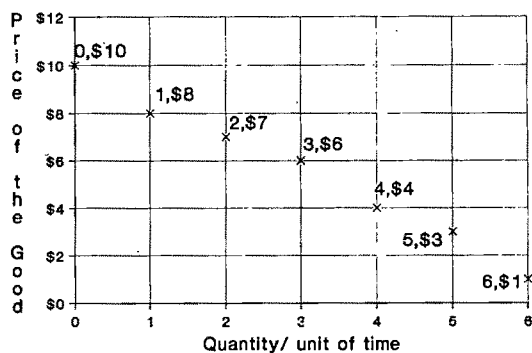

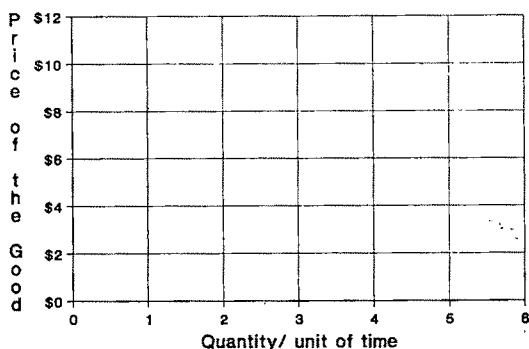

Figure 1. Demand sequence in a microeconomic theory section of the course

ity and accuracy. This careful and accurate drawing is important in a freshman-level class in which students are inexperienced at drawing graphs. For the supply-demand model, the computer is programmed to draw the vertical (price) axis beginning at the top; the horizontal axis from left to right; the demand curve downward from left to right; the supply curve upward from left to right; the equilibrium quantity from the supply-demand intersection downward; the equilibrium price from the supply-demand intersection to the left one line at a time at the same speed and direction as on the chalkboard.

The last section deals with various specializa-

tion areas within agricultural economics, such as marketing, natural resource economics, agricultural policy, and rural development. This section of the course uses a combination of text images, charts to depict data, as well as drawn graphics images similar to those in the micro-theory section.

System Advantages

The system has three primary advantages for the instructor and the students.

(a) *Improved Course Structure and Organi-*

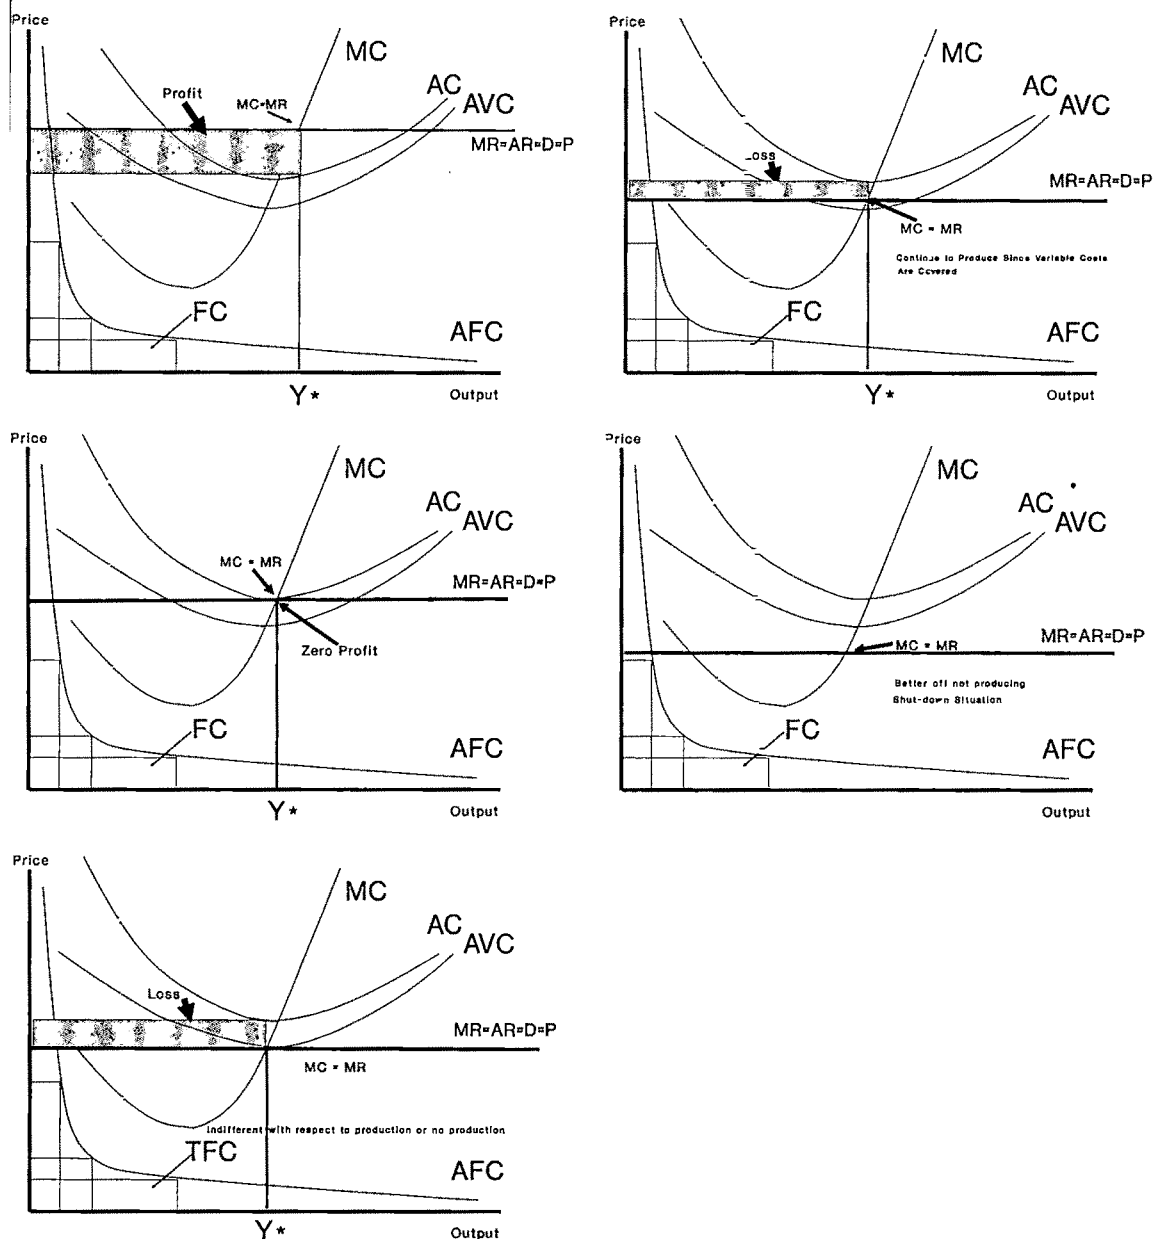

Figure 2. Cost sequence in microeconomic theory section of the course

zational Flow. The flow of the subject matter presentation is logical and sequential. With the combination of study guide and computer-generated slide show, students do not have to determine where a lecture will lead on any given day. If an instructor is absent for a class, another professor can readily substitute without disrupting the flow of the class presentation. If students miss class, they at least know what topics they missed and have the study guide material.

(b) Improved Accuracy of Student Notes. The basic set of notes and graphs from the study guide is correct. Students do not need to worry if they have copied accurately from the chalkboard. This is particularly important advantage for students who miss a lecture.³

³ A concern might be that with access to the detailed study guide, students would tend to miss class more frequently. There is no longer any uncertainty about the topics of any specific lecture. Class attendance is not mandatory. However, we have not observed any

(c) *Improved Use of Class Time.* The course content and depth of coverage has remained the same with the new technologies. However, the utilization of class time has changed somewhat. Now instead of spending valuable class time trying to accurately draw graphs, the instructor can concentrate on explaining the graphs. Instead of copying from the chalkboard, students can concentrate on what the instructor is saying. More emphasis can be placed on interpretation and analysis, with less time devoted to copying the instructor's notes. There is more time to teach processes rather than skills.

Technical Implementation Issues

Computers and Projection Equipment

We have experimented with operation of the course from IBM-compatible computers of various speeds including 8088, 80286, and 80386 machines. With a 80386 machine, special effects, such as line draws mimicking a chalkboard presentation, occur so rapidly that some of the effectiveness is lost. We have found that an 16 Mhz 80286-based machine operates slowly enough that the special video effects realistically mimic how an instructor might draw on the chalkboard and yet fast enough so that the instructor can move through a sequence of screens rapidly, if needed (such as might be desired for a review session). It is not possible to adjust the speed of the draw within the software.

One of the key elements of the technology that makes the approach feasible is the small size (in bytes) of the individual files comprising the individual video screens. Depending on the complexity of the displayed images, these individual files are usually from only 1K–3K. Thus, the entire course needs only 3 megabytes of space on a hard disk. This is because the file comprising a screen image is the data needed to draw the graph, not the actual image. In addition to reducing the space required to storing the screens comprising the course, graphs in the study guide are of high quality, limited only by the resolution of the printer.

All of the lessons are in color. Until recently, we used a monochrome video projector capable of EGA resolution; but in the fall of 1989, we

began using a high-resolution color video projector in a classroom with lighting modified for video display (fig. 3). Video quality from this unit is identical to that from an EGA/VGA computer monitor. We have also experimented with EGA/VGA LCD pads and a conventional overhead projector as a light source, and these units function about the same as the monochrome display projector, with a similar cost. Any of this equipment could be effectively used in the classroom.

Kropp (1973b, p. 760) suggests that "the investment which an academic department wishes to make in instruction is a major factor in determining what teaching methods will be used," and that "computer-based and video courses require heavy initial outlays for producing instructional materials and acquiring equipment." Fortunately, the cost of the equipment we used, though not insubstantial, is declining and is now cheap enough to make investments in the new technologies possible for many, if not most, departments. Cost is one advantage for a monochrome display projector or overhead projector pad (\$2,500 versus \$10,000 for the color projector),⁴ but the line-drawing capabilities and other special video effects are less appealing in monochrome than in color. Most departments undoubtedly already have access to the laser printer needed to produce a high-quality study guide such as the one we developed.

Operational Procedures

The day-to-day equipment operation procedures are new for the instructor, but because the projector and computer are permanently installed in the classroom, less than five minutes are needed to start the equipment before each class. Lessons are copied to the hard disk in the classroom before the semester begins. Computer software is loaded as soon as power is supplied to the computer and projector. The instructor merely selects the "slide show" option from the main program menu and goes to the subdirectory containing the slide show lesson for that day. If necessary, a mouse on the computer functions like a remote control on a slide projector per-

reduction in the proportion of students attending class on any specific day since the system was adopted. In some instances, attendance was up. We estimate that class attendance has averaged about 70% for the semester with the new teaching system.

⁴ Five years ago a color projector capable of EGA/VGA resolution would have cost \$50,000, an amount that would not have been a feasible investment for most agricultural economics departments. Furthermore, a microcomputer capable of generating the high-resolution images would have been considerably more expensive. Most important, easy-to-use and inexpensive software for generating the lessons was not available.

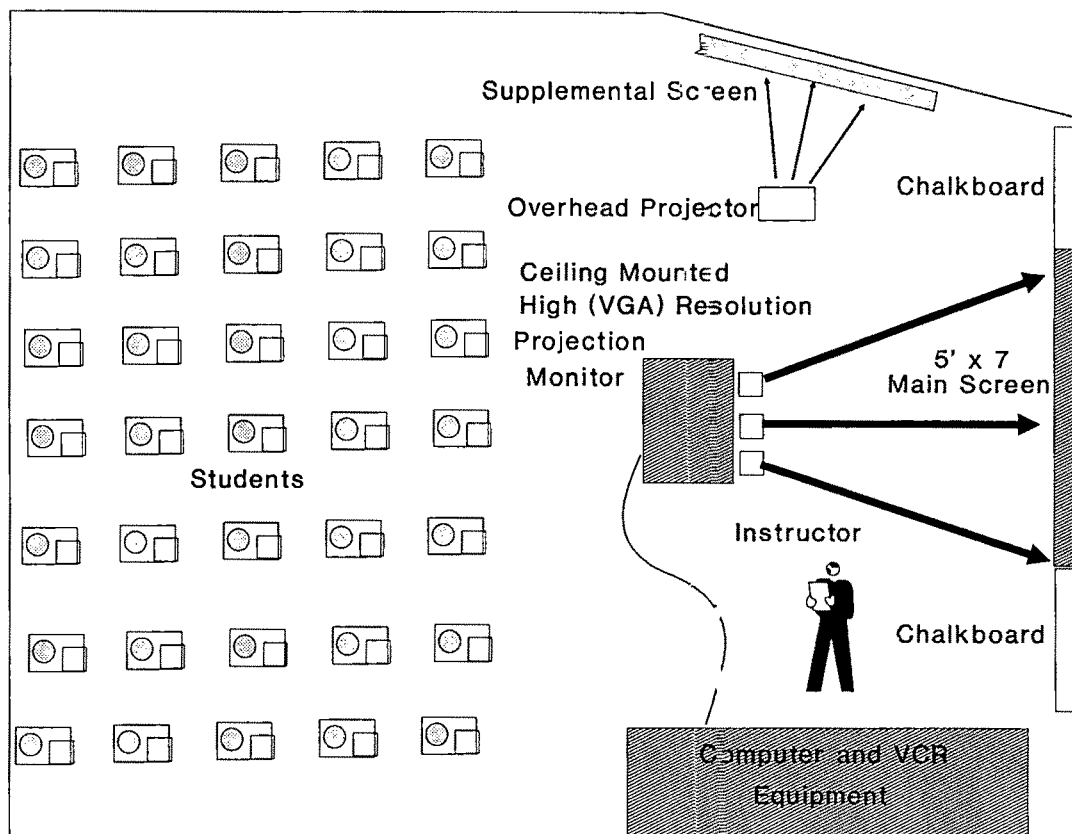

Figure 3. Classroom layout

mitting the instructor to back up during a lecture.

Mixed-media approaches are also possible with the system, and the instructor need not rely entirely on the video display. For example, overhead transparencies are occasionally useful in teaching the course to quickly review a portion of a previous lecture. Any of the 1,200 computer slides comprising the course can be made into a transparency to supplement the video presentation or as a backup system in the event of equipment failure. These transparencies can also be made in color using a pen plotter. An effective classroom presentation also can be made using conventional color slide projectors, as the software is capable of sending text and graphics images to a color slide maker.

Evaluation of Effectiveness

A key concern is the effectiveness of the teaching approach relative to conventional methods of instruction. Do the students prefer the new

approach? Do they learn better? Both instructors have had previous experience teaching the course using hand-drawn transparencies and an overhead projector. During the fall semester, 1989, an evaluation survey was conducted of the GEN 101 students. All but one of the forty-five students completing the class provided responses to the survey. The survey was designed to examine student reaction to the technologies employed as learning aids in the course and to provide students with an opportunity to suggest further course improvements.⁵

Each of the items used in the course (including the new technologies) represents an investment by either the university, the student, or both. This is also true for conventional instructional methods. To illustrate, the purchase of a text-

⁵ In addition to the class evaluation reports reported here, the college also conducts its own evaluation of instructors using a five-point scale. These evaluations focus heavily on the personality of the instructor, how the instructor relates to students, and course organization. Since the new system has been put in place, both instructors have experienced an increase in their average scores on this evaluation of approximately 0.3 to 0.4 of a point.

book is an investment by the student. The computer and display equipment is an investment by the university. Comprehensive worksheets must be graded either by the instructor or a teaching assistant, both of whom are funded by the department. It is important to know which investments yield the greatest effectiveness.

The survey asked students to identify the instructional methods used in the course that most enhanced their learning. The instructional methods evaluated are listed in table 1. Students were asked to use a five-point scale to evaluate the importance of each of these methods in helping them learn the material contained in GEN 101. The components evaluated and the results are presented in table 1. The scale was 5 = very important; 4 = important; 3 = neutral; 2 = unimportant; 1 = very unimportant.

Results of Evaluation

The evaluation occurred during the final week of classes; hence, student reaction to the importance of the final exam in enhancing learning could not be evaluated. Results of this portion of the evaluation are contained in table 1. Based

on the mean values for each response, the following conclusions were reached about the technologies employed.

Students felt strongly about the importance of the worksheets in enhancing learning. This was the first semester we employed worksheets which dealt with all the material contained in the course. Even though answers to questions contained in many of the worksheets could be obtained readily from the study guide, students still felt that the worksheets were the most important learning aid. The study guide also received high marks from students as a learning aid, and students ranked the study guide higher than the computerized slide shows upon which the study guide was based. Based on means from the survey results, we concluded that the animations of the diagrams used in the course made possible by the computer were successful in enhancing learning for the students.

In comparison with the other class materials, the textbook (available to students on reserve in the agricultural library) fared poorly as a learning aid, despite specific assignments related to the lectures and instructor admonitions to read the assignments. Students largely felt that the textbook assignments were redundant. With the

Table 1. Student Response to Learning Effectiveness for Specific Teaching Technologies Used in GEN 101, Fall Semester, 1989

Teaching Technology ^a	Respondent Mean ^b	Standard Error ^c	Percent Ranking as					Did Not Rank
			Very Important				Unimportant

9. Supplemental slide shows for help on worksheets	3.12	0.20	18.2	18.2	31.8	15.9	13.6	2.3
10. Specific textbook assignments	2.32	0.22	9.1	13.6	20.4	18.2	34.1	4.5
11. Textbook on reserve	2.07	0.22	2.3	6.8	22.7	31.8	36.4	0

^a We would classify technologies on lines 4, 6, 8, and 9 as new technologies; those on lines 3, 5, 7, 10, and 11 as old technologies; and those on lines 1 and 2 as old technologies that have been adapted to take advantage of elements of the "new" technologies. Without the computer-generated slide shows, it would have been difficult to develop the coordinated study guide and set of worksheets.

^b Respondents exclude those who did not rank a technology; $n = 44$.

^c The smaller the standard error, the greater the agreement among respondents with respect to the ranking.

Table 2. Specific Student Rankings of Instructional Components of GEN 101

Instructional Component	Mean Ranking	Standard Error
Worksheets	2.48	0.33
Study guide	3.27	0.40
Computer-generated slides	4.09	0.28
Lecture itself	4.18	0.41
Hour exams	4.52	0.30
Pop quizzes	5.11	0.34
Supplemental slide shows	6.59	0.46
Studying with classmates	6.61	0.49
Old exams	7.14	0.47
Textbook	7.86	0.39

* Students were asked to rank each item from 1 to 10 in terms of its importance in helping them learn the material presented in GEN 101. A 1 indicates a high-ranked item, 10 a low-ranked item. The lower the score, the higher the ranking. The smaller the standard error, the less disagreement among the students with respect to the ranking.

computer slides, study guide, and worksheets, we have been unsuccessful in convincing students of the value in reading from a conventional textbook. However, the results should not be interpreted as a rejection of the use of textbooks in beginning courses. Rather, if the instructor wishes to use a textbook to supplement the written class notes, the instructor needs to determine exactly how the students should use the supplemental textbook material. It is not enough to assume that students will be enthusiastic about seeing another approach to the material contained in the lecture and study guide.

The two supplemental slide shows did not receive high marks as learning aids, even though they were closely linked to, and helpful in,

completing the two most difficult worksheets. The supplemental slide shows also introduced the students to the undergraduate computer lab. However, less than a third of the class indicated that they had gone to the computer lab to view at least one of the slide shows.

Students were then asked to rank ten of the methods with respect to importance in helping them learn the material presented in GEN 101. Results are presented in table 2. Results from the student rankings were largely consistent with the earlier findings. Once again, the worksheets, the study guide, and the computer-generated slides ranked as the top three items; the textbook and old exams ranked lowest.

Finally, students were asked to react to the computer-generated slide shows as a primary mode for lecture presentations. Students could select from four responses or write their own response. These responses are listed in table 3. The strong positive reaction by students to the computer-generated slide shows is evident. Nearly one-half (21 students or 47.7%) indicated that the computer-generated slides were superior to any other means they had seen instructors use to present lecture material. Only two students did not like the slides at all, and one other student responded that the instructor should rely primarily on a chalkboard or an overhead projector instead. Most of the remaining students indicated that, while they preferred the computer-generated slides most of the time, an occasional presentation on the chalkboard or on an overhead would have strengthened the course. These students might have liked one of the "mixed media" approaches.

Table 3. Specific Student Responses to Computer-Generated Slide Shows

- The computer-generated slides were superior to any other means I have seen instructors use to present lecture material.*
21 selected this response, representing 47.7% of the class.
- The computer-generated slides were OK, but sometimes I wished that the instructor would use a chalkboard or a visual on an overhead projector to make a point.*
13 selected this response, representing 29.5% of the class.
- I wish that the instructor would rely primarily on the chalkboard or an overhead projector for his presentations. The computer is OK to supplement the lectures on some material, but should not be used everyday.*
1 person selected this response, representing 2.3% of the class
- The computer-generated slides were a bomb. Why can't we have ordinary lectures in GEN 101?*
2 students selected this response, representing 4.5% of the class
- None of the above statements adequately represents my response.*
6 students, representing 13.6% of the class provided other responses. Most of these were qualified endorsements similar to statement number 2.

Suggestions for Course Improvement

In order to identify possible improvements in the course, students were asked, again on the basis of a five-point scale, whether they agreed or disagreed with a series of statements each suggesting a change in the course. Results are presented in table 4. Particular emphasis was placed on eliciting responses indicating dissatisfaction with the computer-generated slide shows in favor of returning to a conventional presentation mode. Most of the students were not in favor of going back to the chalkboard and overhead projector. Students again indicated that the study guide based on the computer-generated slides was adequate without a textbook. The suggestion with the strongest support was for creating a file of old exams. Other suggestions receiving considerable support among students were for spending more time on class discussion and going over exams, quizzes, and worksheets.

Impact on Student Performance on Exams

An effort was made to determine if students performed better on exams with the new system in place. Exam scores for the GEN 101 class were compared for the fall semester 1987, before the

system had been implemented and fall semester 1989, when the complete system was used. A number of qualifications are needed when making such student performance comparisons. There is no assurance that the students enrolled in the class in the fall 1989 were identical in ability to those enrolled in the fall of 1987. Another difference was that the enrollment in the fall of 1987 was somewhat higher than in the fall of 1989 (68 versus 45 students). However, the instructor was the same in the fall of 1987 as in the fall of 1989, the course content in terms of topics covered and level of difficulty was similar. Examinations were also similar in structure and level of difficulty in both years and consisted of a combination of true and false and multiple choice questions, short answer essays, problems, and questions that required students to draw graphs.

Table 5 reports the mean exam scores for two hour exams and the final exam under the old and new system. Mean exam scores were significantly higher for the first hour exam (83.29 in 1989 versus 74.31 in 1987) and for the final exam (82.44 in 1989 versus 74.66 in 1987). No significant difference was found for the second hour exam (72.60 in 1989 versus 74.22 in 1987). These data provide at least a small amount of evidence to support the hypothesis that the system had a positive impact on learning.

Table 4. Specific Student Suggestions for Improving GEN 101, Fall Semester, 1989

Suggestion	Mean	Standard Error	Percent Responding				Strongly Disagree 1	No Response
			Strongly Agree 5	4	Neutral 3	2		
Create a file of old exams	4.09	0.16	43.2	31.8	20.4	0	4.5	0
Study guide adequate without book	4.05	0.18	47.7	20.5	20.5	4.5	2.3	2.3
Spend more time going over worksheets	3.43	0.15	11.4	43.2	27.3	13.6	4.5	0
More class discussion is needed	3.30	0.14	11.4	25.0	47.7	13.6	2.3	0
Spend more time going over exams and quizzes	3.23	0.16	15.9	15.9	47.7	15.9	4.5	0
More worksheets should be used	2.98	0.18	15.9	9.1	38.6	29.5	6.8	0
Use the chalkboard more	2.77	0.17	9.1	11.4	38.6	29.5	11.3	0
Spend more time going over supplemental slide shows	2.70	0.17	4.5	20.5	31.8	22.7	18.2	2.3
Pop quizzes should not be used	2.67	0.21	13.6	9.1	27.3	22.7	22.7	4.5
Use an overhead projector more	2.61	0.19	13.6	6.8	22.7	40.9	15.9	0
Use computer-generated slides less	2.05	0.15	4.5	2.3	18.2	43.2	31.8	0
Should require textbook purchase	1.93	0.19	6.8	6.8	11.4	20.5	52.3	2.3
Worksheets need not be graded	1.61	0.11	0	13.6	34.1	52.3	0	0
Quiz and test questions should come from the textbook on reserve	1.52	0.12	0	2.3	11.4	22.7	63.6	0
Worksheets should not be used	1.52	0.14	0	6.8	6.8	18.2	68.2	0

<i>F</i> -test for equal variances: <i>F</i> = 1.33 with <i>DF</i> 67, 44. Probability > <i>F</i> = 0.288				

Concluding Comments

It is both possible and practical to develop a course based on computer graphics as the primary medium of instruction employing currently available computer, electronics-imaging, and software technologies. The survey results revealed that the combination of computer-generated slides along with a coordinated study guide and set of worksheets provide learning opportunities beyond a conventional chalkboard presentation supplemented with textbook assignments. Survey results provide strong evidence that the students prefer the new teaching approach. In addition, some evidence suggests that students learned more when the innovations were employed.

The development of the video screens for the lecture presentation and study guide was a part-time effort by one of the instructors over a six-month period. Although the software used is simple to use, the speed at which the instructor can create the video images improves significantly with practice. The last lessons in the course were developed far more quickly, and with greater ease and accuracy than were the first lessons. Once the instructor has become skilled with

the capabilities of the software, a typical lecture can be developed in perhaps two hours. Only lessons involving the use of graphs based on secondary data take longer. This is not inconsistent with the amount of time an instructor would ordinarily use to prepare a lecture for a freshman-level course employing conventional techniques.

Supply Response Under Proportional Profits Taxation

John Quiggin

A striking result in the theory of the competitive firm under certainty is the proposition that a proportional profits tax (with full offsets for losses) will have no impact on optimal output. This result does not apply under uncertainty. It is shown that, under constant or increasing returns to scale, a proportional profits tax will yield an unambiguous expansion in output. The same result is shown to hold for the more general rank-dependent expected utility (RDEU) model.

Key words: firm scale, risk, uncertainty.

A striking result in the theory of the competitive firm under certainty is the proposition that a proportional profits tax (with full offsets for losses) will have no impact on optimal output. The nondistortionary properties of such a tax have been the basis of a large literature incorporating attempts to devise a real tax which approximates the theoretical ideal as closely as possible (e.g., Brown).

This result does not apply under uncertainty. In his seminal expected utility analysis of the firm under uncertainty, Sandmo claimed that a proportional profits tax would increase or decrease output according to whether the coefficient of relative risk aversion is increasing or decreasing. Katz pointed out that this result was erroneous and proposed several complex conditions involving both absolute and relative risk aversion. In their recent survey of the theory of the firm under uncertainty, Robison and Barry use a mean-variance approximation to the expected utility (EU) model to examine this question and conclude that the impact of a proportional profits tax is ambiguous except in the restrictive special case of constant absolute risk aversion.

The competitive optimal output under certainty is only defined when returns to scale are, at least eventually, decreasing. This situation, however, does not apply under uncertainty.

Quiggin (1982a) shows that, under weak assumptions, a competitive optimal output will exist under constant or increasing returns to scale.¹ This analysis is particularly important in relation to agriculture because many studies have found evidence of increasing returns to scale. The most usual result is the existence of an L-shaped cost curve with an initial region of increasing returns followed eventually by constant returns. (A summary of the literature, along with a critical response, is given by Castle.) Risk aversion is a promising explanation for the observed existence of competitive firms of finite size.

The object of this note is to show that, under constant or increasing returns to scale, a proportional profits tax will yield an unambiguous expansion in output. The same result is shown to hold for the more general rank-dependent expected utility (RDEU) model (Quiggin 1982b, Yaari). The result does not generalize to other general models such as the smooth preferences model of Machina.

The seemingly perverse supply response derived here may seem less surprising when it is considered in the light of the debate over the treatment of risk in public projects following the work of Arrow and Lind. In this literature, the analysis is cast in terms of discount rates. However, there is a direct relationship to the problem

John Quiggin is a visiting associate professor in the Department of Agricultural and Resource Economics, University of Maryland.

The author would like to thank Darrell Hueth and especially Bob Chambers, as well as two anonymous referees, for helpful comments and criticism. They are, of course, not responsible for any remaining errors.

¹ The term returns to scale is sometimes used in the specific sense of the cost structure in relation to a proportionate expansion in all inputs, and distinguished from the case, referred to as returns to size where the least-cost input mix varies as output increases. In this analysis, as in most of the literature on the firm under uncertainty, the term returns to scale will be used in the general sense including returns to size.

of the firm under uncertainty because the more the discount rate is increased to take account of risk, the lower is the level of investment and output. One of the themes in that literature is that a proportionate corporate profits tax makes the government an effective partner in private projects, bearing a share of the risk proportionate to the tax rate (Mayshar). This relationship implies that the discount rate for such projects should be lowered; that is, the number of projects undertaken should be larger than it would be for the same market rate of interest in the absence of a corporate tax rate. Thus, at least in a partial equilibrium sense, this analysis leads us to expect a positive supply response to a proportional profits tax. A similar analysis applies to risk-sharing problems such as those of sharecropping and franchise contracts.

The positive supply response result may also be motivated by considering the case of constant returns to scale. Under constant returns to scale, for any realization of the random price variable p , profit is linear in output α . It is well known (Sandmo, Quiggin 1982a) that, whereas output under certainty is indeterminate in this case, a risk-averse firm under uncertainty will have a finite optimal output. Denote this output α^* and let the associated distribution of profits be $F(\pi|_{\alpha^*})$. Now suppose a tax is imposed at a rate of 50%. By the linearity property of constant returns to scale technology, the distribution $F(\pi/2|_{2\alpha^*})$ obtained at an output of $2\alpha^*$ is identical to the original optimum $F(\pi|_{\alpha^*})$ and is the new optimal distribution.

The Economic Control Problem

The positive supply response result will be proved in the context of a general economic control problem which includes as special cases the problem of the firm under price or yield uncertainty. The firm is required to solve the maximization

$$(1) \quad \text{Max}_{\alpha} E[U(\pi(\theta, \alpha))],$$

where θ is an economically relevant random variable, such as price or yield, and α is a control variable, interpreted here as (planned) output. The profit function π determines the level of profits for given choices of θ and α . In EU theory, the function U is a von Neumann-Morgenstern utility function, here assumed to be concave. It will be assumed that

$$(A.1) \quad \partial \pi / \partial \theta > 0, \text{ and}$$

$$(A.2) \quad \partial^2 \pi / \partial \theta \partial \alpha \geq 0.$$

These conditions will be fulfilled in all the standard versions of the control problem. The first ensures that increasing values of the random variable (e.g., output price) increase profits. This condition is a natural one in most versions of the problem. The second condition ensures that increasing values of the random variable increase the marginal return to the control variable (e.g., output). For the firm under output price uncertainty, we have

$$(2) \quad \pi(\theta, \alpha) = \theta \alpha - C(\alpha),$$

and (A.2) is clearly satisfied. Many more general forms of the profit function will also satisfy (A.2).

The first-order condition for an interior optimum for the problem (1) is

$$(3) \quad E[\partial U / \partial \pi \partial \pi / \partial \alpha] = 0,$$

and the second-order condition is

$$(4) \quad D = E[\partial^2 U / \partial \pi^2 (\partial \pi / \partial \alpha)^2 + \partial U / \partial \pi \partial^2 \pi / \partial \alpha^2] < 0.$$

Given the assumed concavity of U , the second-order condition will always be satisfied if π is concave or linear in α .

It remains to be shown that an interior solution will exist. The decision maker must be sufficiently risk averse to permit the existence of a finite optimal output, while production must be sufficiently attractive that the optimal output is nonzero. Quiggin (1982a) derives necessary and sufficient condition for the existence of a finite optimum. It is assumed that there is, in the limit, a positive probability that increases in the control variable will reduce profit. That is,

$$\lim_{\alpha \rightarrow \infty} \text{Pr}\{\partial \pi / \partial \alpha \leq 0\} > 0.$$

Given this "no easy money" assumption, a fairly weak sufficient condition on the utility condition is $\lim_{\pi \rightarrow \infty} U'(\pi) = 0$. This condition is satisfied by all the constant relative risk-aversion functions and, hence, by any function in which the coefficient of relative risk-aversion is bounded away from zero.

The second requirement is that the optimal output should be positive. A sufficient condition may be derived from the observation that, for small risks, the decision maker will be effectively risk neutral. Thus, if $E[\partial \pi / \partial \alpha]$ is positive in a neighborhood of $\alpha = 0$, a positive level of output will be chosen.

Now let a proportional profit tax, with full rebates for losses, be imposed at a rate τ . Then the problem becomes

$$(5) \quad \text{Max}_{\alpha} E[U(\pi_0(\theta, \alpha))],$$

where $\pi_0 = (1 - \tau)\pi$, with first- and second-order conditions

$$(6) \quad E[\partial U / \partial \pi_0 \partial \pi_0 / \partial \alpha] = 0, \text{ and}$$

$$(7) \quad D = E[\partial^2 U / \partial \pi_0^2 (\partial \pi_0 / \partial \alpha)^2 + \partial U / \partial \pi_0 \partial^2 \pi_0 / \partial \alpha^2] < 0.$$

Implicit differentiation of (6) with respect to τ yields

$$(8) \quad \partial \alpha^* / \partial \tau = (1/D) E[\pi \partial^2 U / \partial \pi_0^2 \partial \pi_0 / \partial \alpha],$$

where, as before, α^* denotes the optimum level of α .

By (A.1), for any α , there is a unique value $\bar{\theta}$ such that $\theta \geq \bar{\theta} \Leftrightarrow \partial \pi / \partial \alpha \geq 0$. Let $\bar{\pi}$ be the value of π given $\theta = \bar{\theta}$; then,

$$(9) \quad \partial \alpha^* / \partial \tau = (1/D) \{ E[(\pi - \bar{\pi}) \partial \pi_0 / \partial \alpha \partial^2 U / \partial \pi_0^2] + \bar{\pi} E[\partial \pi / \partial \alpha \partial^2 U / \partial \pi_0^2] \}.$$

The first expectation on the right-hand side (RHS) is everywhere negative by the definition of $\bar{\pi}$, since $(\pi - \bar{\pi})$ has the same sign as $\partial \pi_0 / \partial \alpha$ for every value of θ . The second expectation may be shown to be positive as follows. Observe that $\partial^2 U / \partial \pi_0^2 = -A \partial U / \partial \pi_0$, where A is the coefficient of absolute risk aversion. Thus,

$$(10) \quad E[\partial \pi / \partial \alpha \partial^2 U / \partial \pi_0^2] = -E[A \partial \pi_0 / \partial \alpha \partial U / \partial \pi].$$

From the first-order condition (6), the second expectation in the RHS of (9) will be zero whenever A is constant. This yields the result, derived by Robison and Barry, that $\partial \alpha^* / \partial \tau \geq 0$ under constant absolute risk aversion.

For the more plausible case of decreasing absolute risk aversion, we may proceed as follows. Let \bar{A} be the value of A when $\theta = \bar{\theta}$. Because A is monotone decreasing, while $\partial \pi_0 / \partial \alpha \partial U / \partial \pi$ is positive if and only if $\theta \geq \bar{\theta}$,

$$(11) \quad E[A \partial \pi / \partial \alpha \partial U / \partial \pi] \leq \bar{A} E[\partial \pi / \partial \alpha \partial U / \partial \pi] = 0,$$

by (6).

Thus, if $\bar{\pi}$ is negative, the entire term in curly brackets in equation (9) is negative. Then, by (8), $\partial \alpha^* / \partial \tau \geq 0$.

When the control problem is that of the competitive firm under output price uncertainty, θ

represents price and the definition of $\bar{\theta}$ implies $\bar{\theta}$ is equal to marginal cost. Profit is equal to output multiplied by price less average cost. Thus, the sign of $\bar{\pi}$ depends on whether $MC < AC$. Under constant returns to scale, $MC = AC$ and $\bar{\pi} = 0$. Under increasing returns to scale, $MC < AC$ and $\bar{\pi} < 0$.

The discussion above yields

PROPOSITION 1. *For the competitive firm under output price uncertainty, given decreasing absolute risk aversion, a sufficient condition for a positive supply response to an increase in the rate of proportional profit taxation is that returns to scale should be nondecreasing.*

For a U-shaped cost curve displaying eventually decreasing returns, the same argument establishes that there will be a positive supply response whenever the initial optimum is in the region of the curve characterized by declining or flat average costs; that is, whenever output is at or below the point at which average costs are minimized. A production point below the cost-optimizing level can never be optimal for the competitive firm in the absence of uncertainty, but it is perfectly feasible when uncertainty is present.

The extension to RDEU preferences is straightforward. Maximization of an RDEU functional is equivalent to maximization of expected utility with respect to a transformed probability distribution. For a problem such as that of a proportional profits tax, therefore, the EU result carries over directly. This technique does not work for the general smooth preferences modelled by Machina. The change in the distribution of income associated with a proportional profits tax will lead to a change in the local utility function with respect to which the first-order condition (6) applies, and this ensures that comparative static results will be ambiguous.

Concluding Comments

The existence of a tax which calls forward a positive supply response might seem like the discovery of a fiscal "philosopher's stone."² However, the analysis presented here does not apply to ordinary forms of capital taxation, such

² The discovery of the philosopher's stone, which would transmute base metals into gold, was a key research objective of the medieval alchemists.

as corporate income taxes. The tax base is pure economic profit, that is, above-normal returns to capital and the tax must include full offsets for firms with below-normal returns to capital. Hence, if a proportional profits tax of the type analyzed here were applied across the board, the net revenue raised would be unlikely to be large and might not even be positive.

The appropriate role for taxes of this kind arises when the tax base is some form of economic rent. As noted in the introduction, proportional profits taxes have been proposed as a means of taxing the rent associated with mineral deposits. A similar approach might be used as a means of financing agricultural developments, such as irrigation schemes, particularly where the returns to farmers are very risky. Rather than selling water rights at market prices, governments could allocate them at low cost and impose a proportional levy on (pure economic) profit. In both mining and agricultural contexts, however, numerous practical difficulties must be overcome before a tax of this kind could be implemented.

An Econometric Model of the U.S. Beekeeping Industry

Lois Schertz Willett and Ben C. French

This paper presents a dynamic econometric model of the U.S. beekeeping industry for policy analysis and economic projections. Data from 1952 to 1984 were used to estimate the model by three-stage least squares. The model indicates that, when the federal price support for honey exceeded the market price, the federal program had a significant impact on several sectors of the industry. A comparison of beekeeper revenue, consumer expenditures, and federal government expenditures suggests the honey support program was an ineffective means of supporting honey prices from 1982 through 1984.

Key words: beekeeping, dynamic, econometric, honey support program, price analysis.

The U.S. beekeeping industry contributes to the nation's food supply by producing honey and by providing pollination services to over 3.5 million acres of fruits, vegetables, oilseeds, and legume seed crops dependent on insect pollination. Insect pollination increases yields on another 63 million acres (Hoff and Phillips). Bees produced 150 million pounds of honey, and pollination services benefited crops with a total value of \$9.3 billion in 1985 (Robinson, Nowogrodzki, and Morse). Beekeeper returns have been affected by government price support policies, imports, and pesticide applications, and potentially may be affected by the spread of Africanized bees. Previous economic studies of the industry by Meade, Cheung, Johnson, Gould, Siebert, Olmstead and Wooten have focused on more limited issues pertaining to externalities and the effects of bees on productivity. McDowell evaluated the impacts of a possible spread of Africanized bees, and the General Accounting Office evaluated the federal price support program for honey; but neither study formulated a model involving estimated supply and demand relationships. Policy analysis and economic projections may be improved by a more complete quantitative modeling framework.

Lois Schertz Willett is an assistant professor of agricultural economics, Cornell University. Ben C. French is a professor of agricultural economics, University of California, Davis.

This research was supported in part by the Giannini Foundation of Economics.

The authors thank two anonymous reviewers for helpful suggestions.

This paper presents a dynamic econometric model of the beekeeping industry. The model is used primarily to gain insight into the economic effects of changing the price support program for honey. It has further potential as a tool in analyzing economic issues involving (a) the possible effects of the Africanized honey bee; (b) the potential effects of bee diseases and parasites such as chalkbrood, tracheal mites, and the varroa mite; (c) the probable effects of pesticides on the industry; and (d) the import market. The theoretical foundations for modeling the production and marketing in the beekeeping industry are presented first. In the next sections the empirical model is defined, and empirical results are presented. Finally, the impacts of a change in the federal support program are discussed.

Conceptual Model

The primary products of the bee industry are honey, beeswax, and pollination services. The primary production inputs are packages of bees and queen bees, transportation services, extraction and handling equipment, and labor. Some beekeepers generate replacement or expansion colonies from their own brood stock. Other beekeepers, especially in colder climates, purchase replacement packages and queens from beekeepers in warmer climates who specialize in producing these products for sale. The theoretical foundations for the equation system re-

quired to model the production and marketing of bee products are outlined briefly in this section.

Supply Response

A generalized production function for beekeepers is

$$(1) \quad F(H, W, S, C, K, L) = 0,$$

where H , W , S are rates of output of honey, wax (a by-product), and pollination services, C is a bundle of inputs associated with (and measured by) the number of colonies, and K and L are other capital and labor inputs. For firms that replace or expand part or all of their colonies with purchased bees and queens, C may be decomposed into a component proportional to the purchase of package bees (B) and queens (Q) and a component associated with internally generated bee replacements. For firms that produce bees and queens for sale, B and Q are added as products.

A generalized net revenue function for beekeeping may be expressed as

$$(2) \quad R = H \cdot P_H + W \cdot P_W + S \cdot P_S + B \cdot P_B + Q \cdot P_Q - C \cdot P_C - K \cdot P_K - L \cdot P_L,$$

where P_H , P_W , P_S , P_B , and P_Q are producer prices for honey, beeswax, pollination services, packages of bees, and queens, respectively; P_C reflects the direct cost of replacing or adding a colony; and P_K and P_L are vectors of prices of other capital and labor inputs. For beekeepers who purchase packages and queens, P_C is a function of P_B and P_Q and transportation charges. The values of B and Q are zero for firms that do not produce packages or queens, and S is zero for firms that do not sell pollination services.

The determination of optimal input and output rates is a two-stage process. Assuming competitive conditions, the first stage involves maximizing expected net revenue over a future time horizon with respect to all output and input choices, subject to the production function. The first stage generates a set of functions which relate planned inputs and planned outputs to the expected prices of all inputs and outputs. It also provides an input demand function for bee colonies which relates the investment in colonies to expected future prices of all products and inputs.

Changes in the price support program for honey could affect beekeepers' price expectations and,

therefore, the profit-maximizing adjustments. Honey price supports have been in place for many years, but generally they were below producer average market prices prior to 1981. Thus, the price support program would have little effect on producer decisions over that period. From 1981 to the end of the data used for estimation (1984), support prices exceeded free market prices. This change could have affected producer investment response and other equations of the system as well. To reflect this effect, we introduced a variable, X , which is zero prior to 1981 and thereafter represents the difference between the support price and the market price. This specification is preferable to using a zero-one dummy variable because the response likely varies with the difference between support and market prices.

With these considerations, the aggregate colony response function is expressed as

$$(3) \quad C = C(P_H^e, P_W^e, P_S^e, P_B^e, P_C^e, P_K^e, P_L^e, X),$$

where the superscript e indicates an expected value.¹ The producer expectation model is discussed with the empirical specifications.

The current-year outputs of bee products (in contrast to the planned outputs determined in the first stage) flow recursively from investments in bee colonies. Second-stage solutions for the bee product mix are obtained by maximizing current net revenue with respect to all outputs and inputs, subject to the production function with colonies (C) given. The result is a set of conditional short-run supply functions plus input demand functions for packages and queens, which express quantities supplied (or demanded) as functions of colony numbers and current product and input prices and the influence of the price support program. That is,

$$(4) \quad H = H(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X),$$

$$(5) \quad W = aH,$$

$$(6) \quad S = S(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X),$$

$$(7) \quad B^S = B^S(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X),$$

$$(8) \quad Q^S = Q^S(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X),$$

$$(9) \quad B^D = B^D(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X),$$

¹ Investments in bee colonies could be influenced by changes in alternative uses of beekeeper resources. However, we could not identify a clear measure of returns to such alternatives.

and

$$(10) \quad Q^D = Q^D(C, P_H, P_W, P_S, P_B, P_Q, P_K, P_L, X).$$

Equations (4) to (8) are conditional supply curves, and equations (9) and (10) are the input demand functions for bee packages and queens.

Allocation of Honey between Processing and the CCC

Beekeepers forfeit their honey to the Commodity Credit Corporation (CCC) when the support price exceeds the market price. However, the allocation does not jump from 0% to 100%, but it increases with increases in the ratio of the support price to the market price. That is,

$$(11) \quad H_C = A(H, SP, P_H) \text{ if } SP \geq bP_H, \\ H_C = 0 \text{ if } SP < bP_H,$$

where SP is the support price and H_C is quantity sold to the CCC. The coefficient b is a value slightly less than 1.0 since some honey may be allocated to the CCC even when the market price is slightly below the support price because of market imperfections, differences in availability and accessibility of CCC storage facilities across the country, and differences in honey quality characteristics. The quantity sold to processors (H_P) is the difference between the quantity produced and the quantity forfeited to the CCC ($H_P = H - H_C$).

Processor Demand for U.S.-Produced Honey

Honey processors obtain raw honey from both U.S. producers and from other countries. Imported honey is not a perfect substitute for U.S. produced honey because of market contracts, concern over dependence on imports, and variations in quality and type of honey. Under the competitive conditions assumed here, the profit-maximizing behavior of processors generates a set of input demand functions which relate the quantity of each input to the expected price of the processed product and the prices of all inputs. The variable X allows for a possible downward shift in demand because of lower reliability of domestic honey supplies when much of it is delivered to the CCC. Hence, the demand for U.S.-produced raw honey (H_P) may be expressed as

$$(12) \quad H_P = D(PP^e, P_H, P_I, P_O, X),$$

where PP^e is the expected price for processed honey, P_H is the price of U.S. raw honey, P_I is the price of imported honey, P_O is a vector of prices of other inputs and X is defined above.

Processor demand for imported honey is expressed similarly to the U.S. demand:

$$(13) \quad H_I = I(PP^e, P_H, P_I, P_O, X).$$

The processor expectation model is discussed with the empirical specifications.

Farm-Level Demand for Beeswax

Beeswax is purchased by bee supply dealers who use the wax in the production of frame foundations and by manufacturing industries for cosmetics, pharmaceuticals, sculpturing, and candles. Imported wax is a strong substitute for domestically produced wax. Hence, the derived demand facing beekeepers expresses the price (P_W) as a function of the quantity of wax (W), the price of imported wax (P_{WI}), and other factors (Y) which may shift demand as seen by

$$(14) \quad P_W = W(W, P_{WI}, Y, X).$$

The variable X allows for a possible shift in wax demand among beekeepers under an effective honey price support program. The price of wax and the quantity demanded of wax are jointly determined. However, the demand equation is expressed as a price-dependent function because the quantity of wax is largely a predetermined variable.

Demand for Pollination Services

The demand for pollination services is derived from the input demand functions of farmers who produce crops requiring these services. This relationship is expressed as

$$(15) \quad S = S^D(P_S, P_F^e, P_Z),$$

where P_S is the price of pollination services, P_F^e is a vector of the expected prices of the products obtained from the services, and P_Z is a vector of prices of other farm inputs.

Demand and Market Allocation of Processed Honey

The annual supply of processed honey consists of the quantity of domestically produced raw

honey (H_P), which is converted to processed honey with little or no loss, the quantity of honey imported (H_I), and inventory carried into the current year (ST). Processor decisions on the amount of the annual supply to market in the current year (H_M) and to carry as inventory to the next year (ST_{t+1}) are made under conditions of uncertainty as to supply and demand conditions applicable to ST_{t+1} . There are no generally accepted theoretical principles to predict processor behavior in the face of this uncertainty. The formulation here is a modification of a model for canned fruit processors developed by French and King. Noting that processors have an opportunity to adjust outputs in $t + 1$, French and King argue that processors attempt to achieve an allocation in t to assure that the price covers the raw product and processing cost. However, they will be influenced further by their price and cost expectations in $t + 1$. The deflated lagged price and cost reflect the most recent market and cost experience and serve as a base for projecting possible sales in year $t + 1$.

With these considerations, a market allocation function may be approximated by

$$(16) \quad H_M = M(H_P + H_I + ST, PP, PP_{t-1}, PC, PC_{t-1}, X),$$

where H_M is quantity of honey marketed in t , H_P is quantity of U.S. honey processed, H_I is imported honey, ST is carry-in stocks, PP is processed honey price, PC is the raw product and processing cost. The variable X is included to test for a possible shift in market allocation decisions under an effective price support program.

Honey processors face a demand function derived from consumer, institutional, and manufacturing uses. With equation (16) normalized on quantity, the demand function is normalized on price as seen by

$$(17) \quad PP = P(H_M, N, X),$$

where N represents other variables (to be defined in the empirical specification) that account for shifts in the level of consumer and intermediary demand. The variable X accounts for possible effects of free distribution of CCC stocks beginning with their accumulations in 1981. Statistics on actual CCC distributions are not available.

Carry-over stocks are determined by the identity

$$(18) \quad ST_{t+1} = H_P + H_I + ST - H_M.$$

Equations (16), (17), and (18) form a simultaneous system.

Total System

With added specifications for how price expectations are formed, plus required identities, and the simplifying assumption that the supply of imported honey (H_I) is nearly perfectly elastic, equations (3) to (18) form a complete system that may be solved for the annual outputs and prices of all honey products, given the values of the exogenous variables and any lagged endogenous variables.

Empirical Model

The equations of the model are specified as linear approximations in the parameters but with some nonlinear identities. The variable X could affect all of the parameters of the equations in which it is included. However, because the observations to test this are insufficient, it is entered as a linear variable affecting only the level of response. Prices are deflated by the personal consumption expenditure deflator. All observations are annual values. The empirically estimated model is presented in table 1 with t -statistics in parenthesis below each coefficient and the equations' Durbin-Watson or Durbin h -statistic presented. The variables are defined in table 2. Estimation procedures are described following the discussion of empirical specifications.

Investment in Colonies

The colony response function, equation (3), is modified for empirical analysis by replacing the input prices with measures of unit production cost and combining the costs and product prices into measures of joint profitability (ratios of revenue per colony to cost per colony) for beekeepers specializing in honey production ($FHOPMT$), pollination services ($FPOPMT$), and bee production ($FPKPMT$) [see table 1, equations (3.2), (3.3), and (3.4) for definitions.] The number of colonies is expressed as a function of expected future values of the profitability measures.

In forming their future profitability expectations, beekeepers are assumed to rely mainly on average profit experience over recent periods.

* In (11.1), the POS function takes the value in parentheses or 0, whichever is larger.

Profit measures averaged over various lags were tested, with a two-year average providing the best predictions of colony numbers. The lagged profit measures for the three beekeeper specializations were combined into a single measure of lagged average profitability (*FACMT2*) (see table 2, equation (3.1)). The variable *X* was not statistically significant in the empirical estimation and was omitted from the final equation.

Data pertaining to diseases, pesticide losses, and extreme weather which may affect colony numbers are incomplete or unavailable, so these effects are reflected as part of an unexplained disturbance.

Beekeepers' desired level of colonies may not be achieved instantaneously because of the time required to fill orders, make deliveries, and obtain capital. Actual and desired colonies are assumed to be related as in the partial adjustment

model. That is, actual colonies in *t* are equal to actual colonies in *t* - 1 plus a proportion of the difference between desired colonies in *t* and actual colonies in *t* - 1.

With these considerations, the colony response function is expressed linearly as equation (3.0) in table 1 where the variables are defined in table 2.

Honey and Wax Supply

As in the colony response function, the price variables in the conditional supply function for honey, equation (4), are converted to measures of unit costs and returns and combined into profitability measures for the three major specializations as seen in equation (4.0) in table 1. The supply of wax is proportional to honey pro-

Table 2. Empirical Model Variable Definitions

Name	Definition	Measure
<i>AHC</i>	Allocation of honey to the CCC	(proportion)
<i>CHOPXD</i>	Exogenous input costs for honey producer	(\$/colony)
<i>*COL_t</i>	Industry colonies	(thousands)
Constant	Intercept	(1)
<i>CPKPYD</i>	Exogenous input costs for package bee producer	(\$/colony)
<i>CPOPXD</i>	Exogenous input costs for pollination producer	(\$/colony)
<i>*DHM</i>	Disappearance of honey	(lbs/person)
<i>DUM65</i>	Dummy in 1965 and after	(0 or 1)
<i>DUM73</i>	Dummy in 1973 and after	(0 or 1)
<i>EH</i>	Exports of honey	(million lbs)
<i>*FACMT2</i>	Profitability ratio for all products in time $t - 1$ and $t - 2$	(dimensionless)
<i>*FHOPMT</i>	Profitability ratio for honey production	(dimensionless)
<i>*FPKPYD</i>	Profitability ratio for package bee production	(dimensionless)
<i>*FPOPMT</i>	Profitability ratio for pollination services	(dimensionless)
<i>ICHPD</i>	Index of costs of honey processing	(1972 = 100)
<i>IHM</i>	Imports of honey	(lbs/person)
<i>M</i>	Population	(millions)
<i>*PHFD</i>	Farm price of honey	(1972\$/lb)
<i>PHID</i>	Price of U.S. honey imports	(1972\$/lb)
<i>*PHMAXD</i>	Maximum farm price of honey	(1972\$/lb)
<i>PHMAXDX</i>	Farm price of honey differential between t and $t - 1$	(1972\$/lb)
<i>*PHRDF</i>	Retail price of honey	(1972\$/lb)
<i>PHRDFX</i>	Retail price of honey differential between t and $t - 1$	(1972\$/lb)
<i>PHSD</i>	Price support for honey	(1972\$/lb)
<i>PHSFARD</i>	Support to farm honey price ratio	(dimensionless)
<i>PPKD_c</i>	Price of package bees (California)	(1972\$/lb)
<i>*PPOD_c</i>	Price of pollination services (California)	(1972\$/service)
<i>PQND_c</i>	Price of queen bees (California)	(1972\$/bee)
<i>PWXD</i>	Price of wax	(1972\$/lb)
<i>PWXID</i>	Price of wax imports	(1972\$/lb)
<i>QDHMM</i>	Quantity of domestic honey marketed	(lbs/person)
<i>QHC</i>	Quantity of honey to the CCC	(millions lbs)
<i>QHF</i>	Quantity of honey	(million lbs)
<i>QHP</i>	Quantity of honey to processors	(million lbs)
<i>QPKCOL</i>	Ratio of packages to colonies in $t - 1$	(lbs/colony)
<i>**QPK(J)</i>	Packages used by (J) producer, where $J = HO$ Honey PK Package bee PO Pollination	(lbs/colony)
<i>QPO_c</i>	Quantity of pollination services (California)	(thsd services)
<i>QQNCOL</i>	Ratio of queens to colonies	(bees/colony)
<i>**QQN(J)</i>	Queens used by (J) producer, where J is as in <i>QPK(J)</i>	(bees/colony)
<i>QSHPM</i>	Total domestic quantity of honey at the processor	(lbs/person)
<i>QWX</i>	Quantity of wax	(million lbs)
<i>QWXM</i>	Quantity of wax	(lbs/person)
<i>*SHP</i>	Stocks of honey	(million lbs)
<i>TRND</i>	Linear time trend	(year, 1952 = 3)
<i>TRND73</i>	Time trend beginning in 1973	(year, 1973 = 1)
<i>**WHO(J)</i>	Honey produced by (J) producer, where J is as in <i>QPK(J)</i>	(lbs/colony)
<i>**WPK(J)</i>	Packages produced by (J) producer, where J is as in <i>QPK(J)</i>	(lbs/colony)
<i>**WPO(J)</i>	Pollination services produced by (J) producer, where J is as in <i>QPK(J)</i>	(services/colony)
<i>**WQN(J)</i>	Queens produced by (J) producer, where J is as in <i>QPK(J)</i>	(bees/colony)
<i>**WWX(J)</i>	Wax produced by (J) producer, where J is as in <i>QPK(J)</i>	(lbs/colony)
<i>WXHOR</i>	Wax to honey production ratio	(lbs/lbs)
<i>X</i>	Dummy variable for support program effectiveness	(0 or 1972\$/lb)

duction as seen in equation (5.0), where $WXHOR$ is an exogenous variable that specifies the ratio of wax production to honey production.

Supply and Demand for Pollination Services

Time-series data on the price and quantity of pollination services are available only for California (the major user of such services). Hence, the pollination component of the model refers only to California, although some pollination services in California may be obtained from beekeepers outside of the state.

The supply equation, (6), is determined jointly with considerations of the demand for pollination services, equation (15). Because there is little or no substitution between pollination and other inputs and because the cost of pollination relative to the total value of crop production is quite small, the demand for pollination services is very inelastic. The primary factors determining the demand for pollination services in California (QPO_C) are the area of land requiring pollination services and the number of pollination services used per acre. The latter increased over the period of study due in part to changes in the crop mix and farmers' greater awareness of the potential benefits of bees. Empirical analysis revealed no significant effect of the pollination price on the pollination services used per acre over the range of observed data. Hence, the demand for pollination services is expressed as an exogenous variable rather than as indicated by equation (15).

With the quantity of pollination services (QPO_C) entered exogenously, the supply function for pollination services contains price as the dependent variable. The price of pollination services ($PPOD_C$) is a function of the price of the service charged in the previous year, the quantity of services demanded (QPO_C), the availability of colonies to provide these services (COL_t), the price received to produce honey ($PHMAXD$), and a time trend ($TRND$) as seen in equation (6.0).

The previous period's pollination price reflects inertia in the system and existing contractual arrangements between farmers and beekeepers. The colonies available to provide the services are based on previous period values since current-year colony numbers are not known at the time pollination prices are set in very early spring. Lagged honey price reflects the trade-off between honey production and pollination services resulting from the foraging intensity of

providing pollination services and the bitter taste of honey from almond pollination. Variable $TRND$ accounts for secular increases in beekeepers' willingness to supply colonies for pollination services. Variable X , reflecting changes in the support program, was not significant in the empirical estimation.

Supply and Demand for Package Bees and Queens

As in the case of pollination services, price and quantity time-series data for package bees and queen bees are available only for California. Therefore, the package bee and queen bee supply relationships refer to California.

Discussions with industry representatives suggested that package bee producers, who have the option of retaining the bees for their own use, base the package price on the price of honey and sell whatever packages are demanded at that price. The price equation is specified as equation (7.0) in table 1. Because the current-year average honey price is not known at the time most packages are sold, last year's price is used in the specification. This price-setting equation replaces the supply equation (7) in the system.

The price of queen bees has been set based on the price of packages, with some modification reflecting the movement of queens relative to the number of colonies. The relationship is expressed as equation (8.0) in table 1.

The demands for package bees and queens are proportional to the number of colonies. However, the proportions vary with the product price, the level of the federal support program and shifts over time that are difficult to measure. The two demand functions are expressed as equations (9.0) and (10.0) in table 1. The ratio of packages to colonies ($QPKCOL$) is in equation (10.0) and the ratio of queens to colonies ($QQNCOL$) is in equation (9.0) to account for the complementarity in the two demands.

A shift in demand for packages occurred in the mid-1960s. The exact cause of the change is unknown, but it could be attributable to increased bee kills from new chemicals and the need for replacement bees or the increased acceptance of starting colonies from packages and shipping these packages through the mail system. The variable $DUM65$, with a value of zero prior to 1965 and one thereafter, was introduced in the package demand equation (9.0) to account for the change.

The demand for queens did not shift signifi-

cantly in 1965 as did the demand for packages. Queens are demanded by beekeepers for a more specialized purpose than packages. As the science surrounding artificial insemination of queens and the isolation of genetic qualities has improved, the increased confidence beekeepers place in queen bees is manifested by increased demand for queens. The effect of this scientific evolution on the demand for queen bees is accounted for by a linear trend variable (*TRND*).

Allocation of Honey between Processing and the CCC

The empirical form of equation (11) is specified by equations (11.0), (11.1), (11.2), and (11.3) in table 1. The *POS* function indicates *AHC* takes the value in parenthesis or zero, whichever is larger.

Processor Demand for Honey

The empirical form of the processor demand function for U.S.-produced honey, equation (12), replaces the vector of processing input prices (P_o) with an index of processing cost (*ICHPD*) and normalizes the equation on price, rather than quantity. The price-dependent form is selected because honey supplies are partially predetermined and the intercorrelation problem among prices is reduced. All quantities are expressed on a U.S. per capita basis. The price processors expect to receive for the processed product (PP^e) is affected by carry-in stocks and imports and perceived shifts in the level of per capita demand. The latter may be indicated by changes in lagged deflated processed product prices and per capita movement. Past period price changes while movement is constant indicate a shift in demand; similarly, increased movement while price remains constant would indicate a shift in demand.

An upward shift in the demand for honey also occurred in 1973 that was not accounted for by the lagged price and movement variables. One possible explanation is a change in the buyer psychology during and following the energy crisis of 1973 and 1974. The variable *DUM73* accounted for this shift. With these considerations, the demand function facing beekeepers is specified as equation (12.0) in table 1.

The demand for imported honey [equation (13)] is a function of the import price (*PHID*), the domestic honey price (maximum of support and

market price *PHMAXD*), and the price at which processors expect to sell the honey. Substituting for expected price as in equation (12) and simplifying, the demand for imported honey can be expressed as equation (13.0) in table 1. The lagged per capita movement of honey (DHM_{t-1}) was not significant in the empirical estimation and was omitted from the final equation. The variable *DUM73* also was introduced in this relationship.

Because of limited data the impacts of foreign supply and demand on U.S. imports could not be evaluated. No statistically significant relationship was found between U.S. import honey demand and exchange rates. To simplify the analysis, import supply is assumed to be approximately perfectly elastic at given prices.

Farm-Level Demand for Beeswax

Equation (14) in the conceptual model is represented by equation (14.0) in table 1. The variable *QWXM* replaces *W*, *PWXID* replaces P_w and *FHOPMT* replaces *Y*. *FHOPMT* accounts for changes in the wax demand from beekeepers. As the profitability of the honey industry increases one would anticipate expansion in the number of colonies and a greater demand for wax frame foundations.

Demand Facing Honey Processors and Their Market Allocation

The market allocation for honey, equation (16), is specified as equation (16.0) in table 1. The quantities imported (*IHM*) are sold currently with no inventory carryover because imports likely are coordinated closely with market demands. The dominant factor affecting the quantity of domestically produced honey marketed is the available supply of domestic honey (pack plus carry-in stocks). An increase in costs from the previous period may lead processors to reduce shipments (and increase carryover) in order to raise current price. If the current price increases relative to the previous period price, current shipments may be increased; if price decreases, shipments may be reduced with the hope that prices will be improved the next period. The change in *ICHPD* was not statistically significant in the empirical estimation and was omitted from the final equation. The *TRND* variable accounts for a general increase in market allocation and reduced average inventory carryover.

The domestic demand facing honey processors is expressed as equation (17.0) in table 1 where *DHM* is defined as equation (17.1).² The data suggest that the per capita demand for honey remained stable until about 1973. It then shifted upward with the onset of high-level inflation and the Arab oil embargo but with a down trend because of increasing health and caloric concerns about sweeteners. The dummy shift variable, *DUM73*, and the trend variable beginning in 1973, *TRND73*, accounted for these complex shifts. *DUM73* has a value of zero prior to 1973 and is 1 thereafter. *TRND73* is a trend variable that is zero prior to 1973, then is 1 in 1973, 2 in 1974, etc.

Because data for the honey industry are available only for calendar years rather than seasonal years, stocks are measured as of January 1. The major domestic honey flow is in the spring and summer. With seasonal year data, April 1 to April 1, the seasonal supply to be allocated is predetermined for a given year. However, with calendar year data, the quantity packed (and therefore the annual supply) is determined simultaneously with the processors' allocation of the processed product, the price of the processed product, the carryover stock level and the demand for imported honey.

In terms of the empirical variable definitions, equation (18) becomes equation (18.0) in table 1, where *SHP* refers to January 1 stocks. Other variables are as defined in table 2.

Empirical Results

The complete model consists of thirteen jointly related stochastic equations, linear in their parameters, and fifteen identities or technical equations seen in table 1. One of the technical equations, equation (3.1), describes *FACMT2*, a calculated predetermined variable rather than an endogenous variable. Some identities, such as equations (3.2), (3.3) and (3.4), are nonlinear. There are twenty-seven current endogenous variables, eleven lagged endogenous variables, and seventeen exogenous variables in the model. The exogenous variables are underlined in the variable definitions (table 2). Lagged endoge-

nous variables are preceded by an asterisk. Parameters indicating the proportion of each product produced by beekeepers specializing in honey production, bee production, or pollination services and parameters indicating the quantity of packages and queens purchased by each specialty are derived from Reed and Horel. They are identified by a double asterisk.

The data are calendar year values for the period 1952 to 1984. Data for 1985, 1986, and 1987 are used for out-of-sample prediction tests. Data pertaining to bee colonies, honey quantities, and prices are U.S. values. Data pertaining to cost of production, prices and quantities of pollination services, packaged bees and queen bees are for California since U.S. values are not reported. Monetary values are deflated by the U.S. personal consumption expenditure deflator. Data pertaining to prices received by honey processors were available for only part of the period of analysis. Therefore, a somewhat longer series of retail prices was used as a proxy for the wholesale prices. Reporting of the retail price series was discontinued after 1979. Hence, the prices for 1980 to 1984 were estimated from historical retail-farm price margins (Willett, pp. 135-37).

The model was estimated by three-stage least squares (3SLS) except for equation (11.1), which involves a limited dependent variable. The existence of a limited dependent variable within a set of simultaneous equations involves complex estimation procedures and restrictions (Amemiya). To simplify the analysis, this equation was estimated by ordinary least squares with data for 1981 to 1984 because this is the period the support program essentially was effective. Separate estimation of equation (11.1) may affect the efficiency of the estimates, but the loss likely is small compared with the gain in estimation simplicity.³

Performance Characteristics

All estimated coefficients have signs consistent with the theoretical specifications of the model. Most are large relative to their standard errors, as indicated by the *t*-statistics in parentheses. The Durbin-Watson or Durbin *h*-statistics for all equations either do not reveal autoregressive re-

² Other sweeteners, such as sugar, corn syrup, and artificial sweeteners, are not considered significant honey substitutes because of honey's unique characteristics (color, flavor, viscosity, moisture retention capabilities, and marketing appeal). Recent promotional efforts by the National Honey Board have increased the attractiveness of honey and its use in food products.

³ Estimation of equation (11.1) by maximum likelihood Tobit for the period 1952-84 yields similar results. The ordinary least squares estimates based on 1981-84 data were used since they provide a closer fit for the period of policy analysis.

ror structures at the 5% significance level or are inconclusive.

The ability of the model to provide reasonably close fits to the historical data used in the estimation was evaluated by static one-period-ahead predictions of the model's endogenous variables. The predictions were made given the values of the exogenous variables, the carry-in stocks of honey and actual values of other predetermined endogenous variables. Most average absolute prediction errors were within 10% of the mean values of the predicted variables.

The stability of the nonlinear model was tested by holding the exogenous variables constant (at their 1984 values) and allowing the model to generate values of the endogenous variables over a future period. All variables approached stationary equilibrium values by the fifteenth time period, suggesting the model is stable.

To test for possible structural changes or specification errors, out-of-sample predictions were calculated for the period 1985, 1986, and 1987, subject to the limitation of available data. The model's predictions were obtained by inserting observed values of right-side variables in each structural equation. When data were not available for some exogenous variables, they were assumed to remain at 1984 values. Actual colony levels for 1986 and 1987 were assumed to remain at 1985 levels because the colonies reported by the U.S. Department of Agriculture (USDA) decreased from 4,325,000 in 1985 to 3,205,000 and 3,190,000 in 1986 and 1987, respectively. This unprecedented drop of 1 million colonies results from USDA's elimination of reporting those colonies of beekeepers with fewer than five hives.

In 1986, a lower loan repayment option allowed producers to repay their loans at a rate below the support rate. Hence, producers were encouraged to repay their loans and sell their honey on the market. Because of the change in the federal honey program in 1986, calculation of the variable reflecting adjustments to the honey support program (X) was no longer consistent with previous years. However, if this variable is set to zero, the model overpredicts several endogenous variables. Because of the continuing uncertainty about the existence of the honey support program, it seems reasonable to hold the variable X at its 1985 value for testing purposes.

The model's predictions, seen in table 3, are reasonably close to actual values and are within the 99% confidence interval suggested by the standard error of the regressions (identified by the S under each equation) for all but three vari-

ables.⁴ The model underpredicts the production of honey (Q_{HF}) in 1987 by an amount inconsistent with the values of the standard error. The 1987 honey crop was large because of excellent weather conditions across the United States. In addition, it appears that by 1987 the depressing effect of the uncertainty surrounding the support program was no longer as strong as it was in 1985 and 1936. Elimination of the effect of the support program in 1987 would mean an increase in the model's prediction of honey production by 47 million pounds. With this alteration the actual level of production would be within the 99% confidence interval suggested by the standard error of the regression.

The 1987 prediction of per capita honey imports (I_{HM}) is also outside the confidence interval. Thus, the federal honey support program did not appear to influence the quantity of honey imported in 1987 as the model suggests. Elimination of this effect (setting $X = 0$) means the model's predictions of per capita imports for 1987 would be 0.250 pounds per person, clearly within the range of the confidence interval.

Finally, the predictions of the per capita quantity of domestic honey marketed (Q_{DHMM}) were out of bounds in 1986. Processors did not increase their marketing of domestic honey as quickly as the model predicts. The model predicts processors would market more of their honey and hold less in stocks than actually occurred. By 1987 the model's predictions were closer to actual values.

Interpretation and Policy Analysis

Flexibilities and elasticities, evaluated at the mean of the data set and at 1980 values, for the model's supply and demand relationships are presented in table 4. The values for 1980 were chosen because that is the most recent year the support program was not effective. The variable $\epsilon_{COL1,PHMAXD}$ refers to colony response to the farm price of honey while $\epsilon_{COL1,FACMT2}$ refers to colony response to average profitability of all beekeeping products. The variable $\epsilon_{QHF,PHMAXD}$ is the conditional supply elasticity for honey given the

⁴ Model predictions might be examined in relation to confidence intervals based on the equation's standard error of the forecast rather than the standard error of the regression. In general, the standard forecast error will not be less than the standard error of the regression. Because the standard errors of the forecast involve complex calculations and the predictions for most variables fall within the reported confidence intervals, these standard errors were not calculated.

Table 3. Comparison of Actual and Predicted Values of Endogenous Variables in the Honey Industry Model 1985-87

	Year	Actual (A)	Predicted (P)	Difference (A-P)
Colony, COL_t	1985	4325.0	4266.1	58.9
Equation (3.0)	1986	4325.0	4303.1	21.9

level of colonies and $\epsilon_{QDHMM,PHRDF}$ is the allocation elasticity for honey given the seasonal supply. The variables f_{PPOD_c,QPO_c} and f_{PQND_c,QQN_c} are the price flexibilities for pollination and queen pricing, respectively. Package price, equation (7.0), is based on the honey price and has no flexibility. The demand elasticity for imported honey ($\epsilon_{IHM,PHID}$) is elastic while the demand elasticities for packages ($\epsilon_{QPKCOL,PPKD_c}$) and queens ($\epsilon_{QQNCOL,PQND_c}$) are inelastic. The flexibilities for wax price ($f_{PWXD,QWXM}$), domestic honey producer price ($f_{PHFD,QHFM}$) and processor price ($f_{PHRDF,DHM}$) are low.

An important problem in estimating the model was accounting for difficult-to-measure shifts in levels of some of the model equations, partly

because of honey price supports and partly because of other structural shifts. With regard to the latter, the price of pollination services, equation (6.0), decreased over the period of the analysis at the rate of 0.191 cents per year. The data suggest that package bee demand, equation (9.0), shifted upward in 1965 although the reasons are not entirely clear. The demand for queens, equation (10.0), has shown a general upward trend due to changes in production practices. The demands for honey, equations (12.0), (13.0), and (17.0), shifted in a complex manner. The demand for processed honey shifted upward about 1973 (consistent with the general structural change for a number of agricultural commodities), but demand trended down fol-

lowing 1973. The negative trend effects in the demand for processed honey likely are absorbed in the coefficients for *ICHPD* and *PHID* in the processor raw honey and import demand equations, equations (12.0) and (13.0), respectively.

The significance of variable *X* in several equations suggests that when the price support for honey exceeded the market price it had a significant impact on several sectors of the honey industry. No direct effect on the number of colonies maintained by beekeepers was evident; but, when the support program was effective, a decrease in beekeepers' supply of honey was reflected by a shift in beekeepers' specializations among honey, pollination, and packages. The demand for packages and queens all appeared to decrease when the support program was effective. The demand for wax and domestic honey decreased as imported products became more attractive. In addition, the demand for processed honey declined due to free CCC disbursements. Apparently, consumers substituted CCC disbursements for market priced honey. The demand for imported honey increased as processors chose not to rely on the uncertain domestic supply. The available supply of processed honey marketed in the current year fell because of the increased uncertainty about market conditions. Hence, the model shows that the federal honey support program caused a substitution of imported honey for domestic honey and shifted large quantities of honey to the CCC.

Table 5 captures actual and predicted values of the key endogenous variables of the model for the period 1982–85 assuming the price support had continued below the market price, i.e., $X = 0$. The years 1986–87 were omitted because of the change of the federal support program. The predictions were made with the estimated disturbance terms entered as exogenous variables. It seems reasonable that the random factors captured by the disturbance would not change under alternative scenarios. Since adding the disturbance term gives the exact prediction for the historical model when *X* is included, the model predictions with *X* equal zero are compared with actual values rather than deterministic predictions.

Without an effective support program the market price for honey (*PHFD*) increased. Yet, this price is still less than the support price beekeepers were receiving under the federal program. In response to the price change, the level of colonies (*CCL_t*) decreases slightly and the price of pollination services (*PPOD_c*) falls. The prices of package bees (*PPKD_c*) and queen bees (*PQND_c*) increase, eventually increasing the profitability of these beekeeping specializations. In response to higher prices and profitability and less uncertainty about the support program, beekeepers use their colonies more intensely and increase their honey production (*QHF*) and the quantity of queens and package bees produced per colony (*QQNCOL*, *QPKCOL*). More domestic honey is sent to the processor and the quantity of honey imported (*IHM*) decreases. As less honey is forfeited to the CCC, free disbursements are not made. The demand for processed honey shifts and the price of honey received by processors (*PHRDF*) increases. Processors market a larger quantity of domestic honey (*QDHMM*).

Without the support program the predicted revenue received by beekeepers for their five products decreased slightly during 1982 through 1984 as seen in table 5. However, in 1985 beekeeper revenue is \$5 million more without an effective support program. Free disbursements by the CCC decreases. Hence, consumer expenditures for processed honey increase because of higher prices and increased per capita consumption of domestic honey. When the support program is not effective, the federal government has a potential savings of \$246 million from 1982 through 1985 (Hoff and Phillips). A comparison of the beekeeper revenue, higher consumer expenditures, and savings to the federal govern-

Put-Call Parity and Arbitrage Bounds for Options on Grain Futures

William W. Wilson and Hung-Gay Fung

Many arbitrage opportunities have become available for market participants since the inception of trading in options. Central to many of these is the put-call parity relationship. If this condition is violated, arbitrage profits could be earned. This paper examines arbitrage possibilities between put and call options on grain futures using two different tests. One is a test of market efficiency over the duration of trading, and the other evaluates arbitrage bounds on individual trading days. In general, the results suggest that the options markets on grain futures are not completely efficient. However, violations varied substantially across contracts and through time.

Key words: arbitrage, market efficiency, options, put-call parity.

Since the inception of options trading on agricultural futures contracts in late 1984 and early 1985, many speculative, hedging, and arbitrage opportunities have become available for market participants. Numerous potential arbitrage opportunities entail simultaneously held long or short positions in puts and calls as well as the underlying futures. Central to the option market is a deterministic relationship between put and call premiums on the same underlying futures contract. This relationship exists because the put, call, and the underlying futures contracts form a portfolio wherein any two of the three instruments can be combined and financed with a riskless bond to replicate the return of the third instrument regardless of the investor's preferences. This relationship is called put-call parity. If the actual premium deviates from the parity price, arbitrage (riskless) profits can be earned.

The original model of put-call parity on stock options was developed by Stoll and later extended by Merton. The model was tested empirically by Klemkosky and Resnick. Option pricing models can be specified for either puts or calls individually. Alternatively, the value of

one type of option (e.g., put) can be deduced from the option pricing model for the other type of option (e.g., call) through put-call parity. The put-call parity relationship binds these markets together.

The most common pricing model for options on commodities is the closed form model developed by Black. This model relates the fair market value of the option premium to five inputs: interest rate, time-to-maturity of the option, underlying futures and exercise price, and standard deviation of the futures price. The standard deviation, which is implied in an option premium, can be obtained by equating the observed option premium and the other four model inputs using an iterative solution technique.¹ If the market is efficient (Fama), the option value should reflect all available information regarding the option and its underlying security. Therefore, participants in efficient markets are not able to trade options or a portfolio of the option with its underlying security to earn riskless profits. If the option model is correct and the market is efficient, the implied standard deviations (*ISD*) derived from puts and calls should be equal and should reflect expectations of the volatility of futures returns over the ensuing time period to maturity.

William W. Wilson is an associate professor, Department of Agricultural Economics, North Dakota State University; H.-G. Fung is an assistant professor, Department of Economics and Finance, University of Baltimore.

Published with the approval of the director of the North Dakota Agricultural Experiment Station, Art. No. 1806.

The authors would like to thank two anonymous reviewers for their helpful comments and suggestions.

¹ Plato (1983, 1985) and others have demonstrated that the interest rate forecast has little impact on the premium. Thus, we treat the observed treasury bill rate as a given parameter in this study similar to other studies (Wilson, Fung, and Ricks).

The purpose of this study is to examine arbitrage possibilities between put and call options on grain futures using two different, yet complementary, tests. In the first test, market efficiency is evaluated using the put-call parity criterion over the duration of trading. If the options markets are efficient and if the model used is appropriate, the *ISD* for puts and calls should be equal. If they are not equal, either the option model used may be inappropriate or market efficiency may be questioned. Although many studies use *ISDs* derived from option pricing models, the appropriateness of the pricing model cannot be completely resolved using this method. In the second part of the paper we examine market efficiency using a test of violation of arbitrage bounds (i.e., put-call parity). If violations of these conditions are observed, riskless profits or market inefficiency can be inferred.

An Ex Ante Volatility Test of Market Efficiency

Put-call parity is evaluated in this section over the duration of trading. *ISDs* are calculated for each strike price and combined using a weighting function. Alternative weighting schemes are presented first, followed by presentation of the data used and empirical results.

Weighting Schemes and the Option Pricing Model

The option pricing model used in this study is based on Black. The call premium, c , can be expressed as

$$(1) \quad c = [FN(d_1) - XN(d_2)]e^{-r(t-t^*)},$$

where

$$d_1 = \frac{\ln(FX) + (\sigma^2/2)(t - t^*)}{\sigma\sqrt{(t - t^*)}}, \text{ and}$$

$$d_2 = d_1 - \sigma\sqrt{(t - t^*)};$$

F is the underlying futures price, X is the strike (exercise) price, r is the riskless interest rate, $(t - t^*)$ is the time-to-maturity, σ^2 is the variance of the futures returns, and $N(\cdot)$ is the cumulative normal density function. The value of the put option is linked to that of the call option through put-call parity (Asay and Wolf). This relation can be expressed as

$$(2) \quad c - p = (F - X)e^{-r(t - t^*)}.$$

From the above equation, the put premium (p) is simplified as

$$(3) \quad p = [XN(-d_2) - FN(-d_1)]e^{-r(t-t^*)}.$$

Examination of the call premium [equation (1)] and put premium [equation (3)], demonstrates that both pricing equations require the same inputs.

Given the four model inputs and the market premium for each (call or put) from equations (1) and (3), the *ISD* in each trading instrument can be estimated. These *ISDs* represent estimates of the *ex ante* volatility of the futures price. Consequently, a separate estimator for *ISD* can be derived for each strike price for each put and call on every trading day. When the *ISDs* from individual strike prices are computed using daily closing option and futures prices, a nonsynchronous measurement bias may occur in the point estimates used to test the null hypothesis.

To minimize this bias, Cox and Rubenstein suggest using a weighted *ISD*, which combines *ISDs* from different strike prices. A number of different weighting schemes are utilized in this study to confirm the robustness of the conclusions. For each day (t) a weighted average of the *ISD* is derived from a portfolio comprised of call options (ISD_j^c) with different strike prices. Similarly, for each day a weighted average of the *ISDs* is derived from a portfolio comprised of put options (ISD_j^p) with different strike prices. The purpose is to test for put-call parity over the duration of the study period by examining whether the weighted *ISD* for calls ($WISD_t^c$) is equal to the weighted *ISD* for puts ($WISD_t^p$).

Given the option premiums and other model inputs, *ISDs* can be computed from equations (1) and (3) for each strike price for both puts and calls using an iterative procedure. Thus, a weighted *ISD* for the option traded at time t can be calculated as follows:

$$(4) \quad WISD_t^c = \sum_{j=1}^N W_{jt}^c ISD_{jt}^c,$$

$$(5) \quad WISD_t^p = \sum_{j=1}^M W_{jt}^p ISD_{jt}^p,$$

where $WISD_t^c$ ($WISD_t^p$) is the weighted *ISD* for call (put) at time t ; $N(M)$ is the number of strikes traded for calls (puts) at time t ; ISD_j^c (ISD_j^p) is the implied standard deviation for a call (put) derived for strike price j ; and W_{jt} is the weighting function used to combine the *ISDs* derived from the different strike prices.

The simplest weighting function applies equal weights to the *ISD* derived from each strike price for individual puts and calls. The equally weighted *ISD* can be expressed as $W_{jt}^c = 1/N$ and $W_{jt}^p = 1/M$. Schmalensee and Trippi argue that results using equal weights are similar to other methods. A number of studies (e.g., Ball and Torous, Beckers, Ramaswamy and Sundaresan, Shastri and Tandon) have concluded that the estimate of *ex ante* volatility derived from the at-the-money option (ATM) are appropriate. In this scheme, the *ISD* for the strike price which is closest to the money is assumed to represent the *ex ante* volatility. This scheme has its own appeal because most trading takes place in at-the-money options. However, some useful information may be neglected in this weighting scheme because options other than those closest to the money are ignored.

Chiras and Manaster suggest using the following weights to combine *ISDs* derived from different strike prices:²

$$(6) \quad W_{jt}^c = (\partial c / \partial ISD_j) \left(\frac{ISD_j}{c} \right) / \left[\sum_{j=1}^N (\partial c / \partial ISD_j) \left(\frac{ISD_j}{c} \right) \right],$$

$$(7) \quad W_{jt}^p = (\partial p / \partial ISD_j) \left(\frac{ISD_j}{p} \right) / \left[\sum_{j=1}^M (\partial p / \partial ISD_j) \left(\frac{ISD_j}{p} \right) \right];$$

where

$$\frac{\partial c}{\partial ISD} = \frac{FT}{2\pi} \exp[-(rT + d_1^2/2)], \text{ and}$$

$$\frac{\partial p}{\partial ISD} = \frac{FT}{2\pi} \exp[-rT + d_1^2/2],$$

where T is $(t - t^*)$, time to maturity.

The logic of the above weighting function is that the option with the largest price elasticity yields the most accurate estimate for futures price volatility; therefore, it is assigned the greatest weight. Other options are included in the average, but the weights are proportional to elasticity. Chiras suggested that weights in proportion to the price sensitivity yield the best estimate

for futures price variation. Thus, the Chiras weighting function is

$$(8) \quad W_{jt}^c = (\partial c / \partial ISD_j) \left[\sum_{j=1}^N \partial c / \partial ISD_j \right],$$

$$(9) \quad W_{jt}^p = (\partial p / \partial ISD_j) \left[\sum_{j=1}^M \partial p / \partial ISD_j \right],$$

where $\partial c / \partial ISD_j$ and $\partial p / \partial ISD_j$ are as defined above.

The Chiras and Manaster method differs from the Chiras method in that the former incorporates the elasticity of future volatility, while the latter only adjusts for the price sensitivity of the volatility. Both of these methods are more complex than the equal or ATM schemes derived above.

Beckers suggests a weighting scheme obtained by minimizing a quadratic function for puts and calls, i.e.,

$$(10) \quad f^c(ISD) = \sum_{j=1}^N W_j^c (c_j - BC)^2,$$

$$(11) \quad f^p(ISD) = \sum_{j=1}^M W_j^p (p - BP)^2,$$

where $BC(BP)$ is the Black model call (put) premium using *ISD* as an input, and $c(p)$ is the actual market call (put) premium. The weighting functions corresponding to Beckers' formulation are

$$W_j^c = (\partial c / \partial ISD_j) / \left[\sum_{j=1}^N \partial c / \partial ISD_j \right], \text{ and}$$

$$W_j^p = (\partial p / \partial ISD_j) / \left[\sum_{j=1}^M \partial p / \partial ISD_j \right].$$

In Beckers' method, selection of *ISD* is different from the other weighting schemes. Given an arbitrary futures volatility and other model inputs, Black call (BC) and put (BP) premiums can be computed using equations (1) and (3). Other values can be computed using alternative futures volatility. Using these values, the quadratic function in equations (10) and (11) can be derived. In Beckers' method the *ISD* is selected that minimizes the quadratic function of the difference between market premiums and its theoretic value is selected.

The simplest weighting schemes either apply equal weight to the *ISDs* derived for each option

² Derivation of $\partial c / \partial ISD$ is available from the authors upon request.

or use the *ISD* derived in the ATM option. The other weighting schemes (Chiras, Chiras and Manaster, Beckers) were designed to give more weight to options whose premium should theoretically be more sensitive to volatility. As a result, options that are far into- and out-of-the money are given the smaller weight. The equal weight scheme assumes that each option is equally important in determining the volatility, and the at-the-money scheme assumes that options other than at-the-money have too much noise to be useful and therefore are given no weight.

For each weighting scheme, we define $\epsilon_t = WISD_t^c - WISD_t^p$, where $t = 1, \dots, n$. If ϵ_t are independently identically distributed random variables with a mean and variance, then the null hypothesis that $H_0: \epsilon_t = 0$ can be tested where $\epsilon_t = \sum_{i=1}^n \epsilon_i / n$. The testing procedure can be performed by invoking the central limit theorem, with the required *t*-statistic defined as

$$(12) \quad t = \frac{\epsilon_t}{S_\epsilon / n},$$

where S_ϵ is the sample estimate of standard deviation of ϵ_t and n is the sample size.³ When the null hypothesis is rejected, we can infer that the option market is not efficient. The maintained hypothesis is that the option model used is appropriate. Violation of this parity condition implies the market forecast of volatility for calls differs from that for puts meaning that market participants would have different forecasts of the same underlying futures price volatility.

Data and Scope of Analysis

Options on selected agricultural futures commenced trading in late 1984. By late 1985 options were being traded on most agricultural futures. For this study four commodities traded at three different exchanges were selected. These commodities include corn and soybeans at the Chicago Board of Trade (CBT) and wheat at the Minneapolis Grain Exchange (MGE) and the Kansas City Board of Trade (KCBT). For each commodity one month was chosen that was consistent with the new crop of the commodity. A single contract month was analyzed (rather than aggregating across contract months) because the nature and extent of informational flows and volatility differ depending on contract month.

Use of options in new-crop months requires traders to forecast volatilities throughout the informational stages of the production cycle.

Daily observations were used, and all of the strike prices traded during the time period were included in the analysis. Strike prices on individual days in which volume was nil were not included in the analysis. The data commenced from about twelve months prior to expiration in the case of the CBT contracts, from January of each year in the case of wheat. The time frame for the latter was slightly shortened because of limited trade in earlier months.

Settlement prices for futures and options were taken from the annual reports of the individual exchanges. The risk-free interest rate was taken from U.S. Treasury bill quotations in the *Wall Street Journal*. Treasury bills were chosen to coincide with the period concurrent with expiration of each option contract (i.e., June, August, October, and November), and converted to an annualized rate, r , for use in the Black model as $r = (10,000/TB)^{360/(t-r^*)} - 1$, where TB is the market price of the treasury bill.

For each strike price, the *ISD* was derived for puts and calls using an iterative solution to the Black pricing model with convergence criterion at ± 0.005 . Given the derived *ISDs* for each strike price, alternative weighting schemes were used to compute an estimate of the *ex ante* market volatility on each day for both puts and calls. The weights and summation for different weighting schemes were derived across all strike prices with nonzero volumes of trade on each day.

Derivation of the *ex ante* volatility using Beckers' weighting scheme was more complex. For each strike, the Black price was calculated assuming alternative values of *ISD* ranging from .07 to .90 by .015. From the Black pricing equation, for example, an option premium was derived for each of the iterated values of *ISD*. These f^c and f^p were evaluated across the alternative values of *ISD*, and the one that minimized f^c and f^p was selected as the measure of the *ex ante* volatility.

The data used in the analysis are described in table 1. Several points of interest arise in comparing volume of trade figures across options and strike prices. First, the distribution of trading across strikes differs for puts and calls. For some options, such as 1987 call in corn, the greatest volume is at the middle strike price, and diminishes for farther in-the-money or out-of-the-money strikes. For other options, the distribution of trade strikes is more sporadic. These results illustrate

³ This testing procedure has been used recently by Johnson.

that the larger in-the-money options have lower trading volume than other options.⁴ A second observation is that in corn and soybeans volume is very unbalanced; the volume in one type of option is substantially greater than the other. As an example, trade in 1986 soybeans calls was two and one-half times that of puts. On the other hand, trading volume was more balanced in the wheat contracts.

Results

The average $ISDs$ for the individual strike prices at each market are presented in table 2. The t -statistic is a test of the null hypothesis that ISD_j^p and ISD_j^c are equal for that particular strike price. In some cases the number of observations was insufficient to conduct the test. The results indicate that the $ISDs$ vary substantially across strike prices. For example, in 1986 corn the ISD_j^p with strikes less than 180, exceeded the corresponding ISD_j^c (i.e., $ISD_j^p > ISD_j^c$ for $j < 180$) while ISD_j^p with strikes greater than 180 ISD_j^p was less than the ISD_j^c (i.e., $ISD_j^p < ISD_j^c$ for $j > 180$). These results suggest that calls were overvalued (undervalued) relative to puts for higher (lower) strike prices. This phenomenon is not apparent in any of the other contracts. The results for soybeans indicate that $ISDs$ for the put and call in 1986 and 1987 are significantly different from each other.

Comparison of the individual $ISDs$ for the 1986 wheat contracts (KCBT and MGE) suggests that the ISD_j^c are all greater than the ISD_j^p for all strikes. This result suggests that puts were undervalued relative to calls during this period. However, for KCBT wheat in 1987 the difference suggests that the puts were overvalued relative to calls (i.e., $ISD_j^p > ISD_j^c$). These results suggest that the extent or nature of arbitrage opportunities may differ substantially in different time periods. In addition, the t -statistic suggests that the $ISDs$ for puts and calls are significantly different in numerous cases. Of the fifty-seven strikes in table 2 where comparison can be made, thirty-two have $ISDs$ for puts and calls that are significantly different indicating violation of the

⁴ Though day-to-day comparisons are necessary to draw this conclusion, it is also reflected in the data in table 1. The reason is likely because options do not have a futures-style margining mechanism. Market makers would routinely offer to buy (sell) in-the-money options at prices less (greater) than the intrinsic value. Prices at which these trades occur would be reflected in the settlement price depending on when the trade occurs and the settlement rules of the respective exchanges.

put-call parity condition. Of the significant comparisons, the ISD^p exceeded the ISD^c in eighteen cases, although the extent of the difference varied across contracts.

The robustness of conclusions on market efficiency is limited when comparing $ISDs$ for individual strike prices. Significant differences may be found between $ISDs$ with some strikes but not with others. Consequently, alternative weighting functions were used for deriving weighted $ISDs$ for puts and calls derived from individual strikes. In addition, the $ISDs$ for the strike price closest to the money (ATM) should incorporate more information than other options.

$ISDs$ based on these different weighting functions are shown in table 3 for each of the contracts. The null hypothesis is that the *ex ante* put and call volatilities are equal. Results of differ-

ent weighting schemes indicate that there appears to be a greater incidence of violation of the put-call parity condition for 1987 than 1986. The frequency of null hypothesis rejection is similar for corn and soybeans in 1986 and 1987. When different contracts are compared, the evidence does not suggest that any one commodity has a greater frequency of efficiency than the others. The frequency of violations in put-call parity is comparable across contracts. In general, the null hypothesis of put-call parity is rejected. With the exception of KCBT wheat, the results indicate there is minimal difference between $ISDs$ derived from puts and calls using the ATM weighting function. This result is consistent with the hypothesis that ATM options reflect more information (e.g., Beckers, Shastri and Tandon) than other studies.

Comparisons across weighting functions are

shown in table 4. These comparisons indicate whether different weighting schemes yield different *ISDs*. Despite the criticism that equal weighting schemes give arbitrary weight, the equal weighting function results in *ex ante* estimates of volatility that are not significantly different from the others. In fact, Beckers' is the only weighting scheme significantly different from the others. In the 1986 soybean contract, for example, the *ISD^P* is about .17 for each of the weighting schemes, whereas that for Beckers' is .10; the *ISD^C* ranges from .17 to .22 but is .37 using Beckers'. Similar differences exist in the other contracts except, perhaps, MGE wheat. For calls, the *ISD^C* using ATM was less than *ISD^C* using the other weighting functions except in 1986 corn. In the wheat market, the *ISD^P* using ATM exceeded the *ISD^C* of the other schemes.

Arbitrage Bound Test of Market Efficiency

Market efficiency is evaluated in this section using a test of violation of arbitrage bounds, i.e., put-call parity. Arbitrage bounds are developed first followed by a presentation of results.

Arbitrage Conditions

In the previous section, a number of different weighting schemes were examined to test market efficiency using the put-call parity condition

over the entire duration of trading of a particular expiration month. These *ex ante* tests represent a test of necessary conditions for market efficiency on options. In this section, a test of arbitrage bounds is conducted for individual trading days as opposed to the duration of trading. If the options violate the arbitrage bounds, market inefficiency can be claimed. Transaction costs are also incorporated in the analysis as a more robust test of market efficiency.

Several earlier studies (Ball and Torous, Bodurtha and Courtadon, Ramaswamy and Sundaresan, Ogden and Tucker) have evaluated arbitrage conditions as tests of market efficiency. In this study, similar procedures are adopted in testing the options markets for grains. Because arbitrage conditions are applicable to American options, issues associated with the choice of option pricing model (i.e., using the European model to price American options) are irrelevant when boundary conditions are used as a test of put-call parity and efficiency. Further, the constant interest rate assumption used in the Black model can also be relaxed.

The arbitrage conditions for options on futures contracts have been derived in previous studies (e.g., Ramaswamy and Sundaresan, Ball and Torous). The assumptions made are the following: (a) investors are price-takers in frictionless markets; (b) they prefer more wealth to less; and (c) a market exists for pure discount bonds of every maturity. No assumptions on the stochastic process of options or their underlying as-

sets (futures or forward contracts) are utilized. Most of the arbitrage conditions are similar to those for options on common stocks (Merton). The arbitrage conditions are presented below.

Arbitrage conditions for call options. The lower bound for the American call is

$$(13) \quad C(t, \tau) \geq \max[O, F(t, t^*) - X],$$

and the upper bound for American call is

$$(14) \quad C(t, \tau) \leq F(t, t^*),$$

where F is the underlying futures price at time t , maturing at t^* ; and C is the American option expiring at time t^* , and $t < \tau \leq t^*$.

Arbitrage conditions for put options. The upper-bound condition for the American put is

$$(15) \quad X \geq P(t, \tau),$$

and the lower bound for American put is

$$(16) \quad P(t, \tau) \geq \max[0, X - F(t, t^*)],$$

where P is the American put price. These arbitrage bounds are valid for (a) any future price distribution and (b) nonstochastic as well as stochastic interest rates.

Parity conditions. The upper parity condition for the put-call relation is

$$(17) \quad C(t, \tau) \leq P(t, \tau) + F(t, t^*) - Xe^{-r\tau},$$

where r is the return on the riskless bond maturing at time t^* . This condition is valid regardless of the future price dynamics and interest rate assumption. The lower parity condition can be expressed as

$$(18) \quad C(t, \tau^*) \geq P(t, \tau) + F(t, t^*)e^{-r\tau} - X.$$

This condition requires a nonstochastic interest rate.

Empirical Analysis and Results

The analysis of arbitrage conditions was conducted on the same contracts and strike prices described above; however, evaluation of some of the conditions required matching data on each particular trading day. Throughout the time series, the volume of trade in either puts or calls, or both, was zero on a number of days. The

evaluation could not be conducted for those days. Thus, the number of trading days in which the violations could be evaluated varied across strike prices and conditions.

In order to profit from a violation of one of the bounds, a trader would take simultaneous positions and would incur transaction costs. The transaction costs are the same as used by Ball and Torous and by Ogden and Tucker on a per contract basis. Adjusting the contract transaction cost by contract size resulted in a round-trip cost of 0.0348¢ per bushel, which was appropriately added or subtracted from the left-hand side of the boundary condition. As an example, to profit from violation of the lower call boundary condition would require taking a long position in the underpriced call, exercising it immediately, and selling the acquired futures. In this transaction, a round trip would be incurred in futures and a one-way trade in calls for a total of .0348¢ per bushel. To profit from violation of one of the put-call parity conditions would require simultaneous positions in (a) writing the overvalued put, (b) buying the undervalued call, (c) borrowing $Fe^{-r\tau}$, and (d) lending X at the interest rate r for time τ .⁵

In each case the percentage of trading days in which violations were incurred and the number of active trading days over which the conditions were calculated. Results for corn are shown in table 5.⁶ As an example, the 200 strike price for 1986 corn had 193 days in which condition 3 could be evaluated. Of those, there were violations of the condition on 9% of the trading days.

As expected there were no violations of the upper call boundary (condition 2). However, the lower call boundary (condition 1) was violated to some extent in nearly all contracts. The largest incidence was in the December 1987 KCBT wheat market in which violations occurred in 7% of the cases. All of the violations of this condition were incurred at lower strike prices. Violations of this condition suggest that arbitrage profits could have been earned by buying the undervalued calls, exercising immediately, and selling the futures.

The upper put boundary was never violated, as expected. However, the lower put boundary was violated frequently. Violation of this con-

⁵ To evaluate the sensitivity of the results to the transaction costs, the boundary conditions were also tested using alternative values ranging downwards to 0¢/bu. The results were very similar to those reported here.

⁶ Results of violations of arbitrage pricing conditions for soybeans and wheat are summarized in this paper and are available from the authors upon request.

a Insufficient data to test condition.

dition suggests that arbitrage profits could be earned by buying the put, exercising it immediately, and buying the futures. The frequency of violations in this condition was greater for the higher-valued strike prices.

Violations of the put-call parity conditions were relatively fewer in corn and soybean contracts. The 1985 MGE wheat contract was violated 16% of the time, but the condition could be evaluated over relatively few days. For the KCBT wheat contract, the violations were as frequent as 38%—60% depending on the strike price. These results in general confirm those presented in the previous analysis and suggest that arbitrage profits could be earned in some contracts and strike prices using a trading rule based on the put-call parity condition. Violation of the upper boundary put-call parity condition would require buying the undervalued put and selling the overvalued call. Opposite positions would be taken if the lower put-call parity bound was violated.

As a generalization, percents of violations aggregated across all conditions excluding the upper bounds are as follows:

Corn	1986	3
	1987	1
Soybeans	1986	4
	1987	1
KCBT wheat	1986	13
	1987	8
MGE wheat	1986	8
	1987	2

These figures illustrate the apparent greater efficiency of the corn and soybean markets relative to that of wheat in terms of violations of the arbitrage boundary conditions. Furthermore, arbitrage opportunities diminished in 1987 as compared to 1986.

The results of arbitrage bound analyses confirm those presented in the previous section which demonstrated that in most cases the *ISDs* for put and calls were significantly different. The frequency of violations of arbitrage bounds in the grain options markets tend to exceed those of other contracts. Ogden and Tucker, for example, showed that British pound currency options had the most frequent violations at 3.1%, while others were violated less than 1% of the time. Ball and Torous observed violations in arbitrage conditions in gold and sugar in 7.56% and 6.03% of the observations, respectively.

Concluding Comments

Two different yet complementary tests on the put-call parity condition for the selected grain

option markets were conducted in this study. The first was a test of the equality of the *ISD* between put and call options over the duration of the study. Results indicated that various measures of *ex ante* volatility of futures price (*ISD*) over the duration of trading differed significantly across put and call options. The second test was to determine the extent to which arbitrage bounds were violated on individual trading days. The analysis demonstrates that riskless profits could likely be earned by traders even after transaction costs.

The underlying motivation of each of these tests is the fundamental put-call parity relationship; however, the formulation of the empirical tests differs. The test of the equality of *ISDs* derived from puts and calls is a test of market efficiency over the entire duration of trading options for a particular expiration month. The test for violations in the arbitrage condition is a direct test of the put-call parity condition (as well as other arbitrage bounds) for individual trading days, as opposed to the duration of trading. In addition, the results of this test are independent of the choice of the option pricing model, and transaction costs are incorporated. Rejection of the null hypothesis using the first test, *vis-à-vis* the arbitrage bound test, is stronger. This finding may be due to bias in the European option model for pricing American options. Because the arbitrage bound test is free from such model bias, it is the preferred procedure for exploring the parity conditions.

Results of these two tests suggest substantial evidence to reject the put-call parity condition in these markets. These findings imply the wheat option market is not as efficient as other option markets (e.g., currency options) and arbitrage profits are likely to exist. This inefficiency may be temporary because of the newness of the grain option market, as is suggested by the reduction in the percentage of violation of arbitrage bounds in 1987 versus 1986 contracts. These findings also could be biased as a result of a nonsynchronization of data. Options and futures settlement prices were used to analyze efficiency or arbitrage opportunities of these markets. Therefore, the reported bias may not be realizable because (a) the bid-ask spread, an important component of transaction cost; (b) the market impact on options and futures prices; and (c) the time lag in execution of a buy and sell order for arbitrage opportunities are all ignored. The above issues can only be resolved via time-stamped intraday transaction data, which are not easily available. Future research using transaction data

to test efficiency in these markets should be encouraged and warranted.

Production, Hedging, and Speculative Decisions with Options and Futures Markets

Harvey Lapan, Giancarlo Moschini, and Steven D. Hanson

This paper analyzes production, hedging, and speculative decisions when both futures and options can be used in an expected utility model of price and basis uncertainty. When futures and option prices are unbiased, optimal hedging requires only futures (options are redundant). Options are used together with futures as speculative tools when market prices are perceived as biased. Straddles are used to speculate on beliefs about price volatility and to hedge the futures position used to speculate on beliefs about the expected value of the futures price. Mean-variance analysis in general is not consistent with expected utility when options are allowed.

Key words: futures markets, hedging, options, price uncertainty, risk.

One extension of Sandmo's expected utility model of the competitive firm under price uncertainty considers the use of futures or forward contracts. Danthine; Holthausen; and Feder, Just, and Schmitz show that without basis uncertainty the optimal output level is not affected by price risk; also, with an unbiased futures price, the optimal hedging level of the competitive firm is the full hedge, while a biased futures price will result in a partly speculative hedge. Related works include Batlin, who allows for basis risk in the form of imperfect time hedging; Paroush and Wolf, and Antonovitz and Nelson, who consider basis risk with the simultaneous availability of futures and forward contracts; Grant, Honda, Losq, Newbery and Stiglitz, and Rolfo, who allow for production uncertainty; Chavas and Pope, who allow for production uncertainty and hedging costs; and Karp, who considers the problem in a dynamic setting.

This paper provides a further extension of this analysis by allowing options as a means of coping with price risk. With the introduction of commodity options on futures for many commodities in the 1980s, this problem appears rel-

evant to a number of production settings, especially in agriculture. Specifically, this paper considers the simultaneous choice of a production level and of hedging levels of futures and options within the general expected utility model. The model allows for basis uncertainty, but the production process is assumed to be nonstochastic.

Optimal hedging when options are available is considered by Wolf in a linear mean-variance framework without including production decisions.¹ The mean-variance framework has been employed in a number of risk management studies. Under certain assumptions, this framework is consistent with expected utility maximization (Meyer, Robison and Barry). However, the inclusion of commodity options in a decision maker's portfolio leads to a violation of the two main conditions for a mean-variance representation of expected utility. First, options truncate the probability distribution of price so that the argument of the utility function, profit or wealth, is not normally distributed even if the random price is normal. Second, the use of options generally means that the argument of utility is not monotonic in the random attributes. Thus, relaxing the mean-variance framework appears desirable to analyze options in a hedging problem.

Harvey Lapan and Giancarlo Moschini are a professor and an assistant professor, respectively, Department of Economics, Iowa State University. Steven D. Hanson is an assistant professor, Department of Agricultural Economics, Michigan State University.

This is Journal Paper No. J-14133 of the Iowa Agriculture and Home Economics Experiment Station, Project No. 2953.

The authors thank Robert Myers and the *Journal* reviewers for their constructive comments.

¹ Wolf also reports simulation results based on the logarithmic utility function.

The paper is organized as follows. A model of production and hedging with both futures and put options is formulated. Some general results are derived for the pure hedging case in which producer price expectations agree with those embodied in the market price of futures and options. This is followed by an analysis of how changes in asset prices (or expectations) affect optimal portfolios under constant absolute risk aversion (CARA). Next, the model is reformulated in terms of futures and straddles. This reformulation highlights the impact that individual beliefs have on speculative decisions, particularly on the use of options, and illustrates the limitations of mean-variance analysis. The concluding section summarizes the main contributions of the paper.

Production and Hedging with Futures and Options

The notation is defined as follows: y is the output quantity produced, x is the futures quantity sold, z is the put option quantity sold, p is the futures price at the end of the period, f is the futures price at the beginning of the period, b is the local cash price (including basis risk) at the end of the period, r is the put option price (premium), k is the strike price, v is the terminal value of a put option, π is the profit at the end of the period, and \sim denotes a random variable. Because one can construct a synthetic call using futures and puts, attention is restricted to put options only. Also, for simplicity, only one available strike price for the option is considered.

The random end-of-period profit of the firm using both futures and put options can then be written as²

$$(1) \quad \pi = \tilde{b}y - c(y) + (f - \tilde{p})x + (r - \tilde{v})z,$$

where $c(y)$ is a strictly convex cost function dual to a concave production function,³ and \tilde{v} is the terminal value of a put option, defined as

$$(2.1) \quad \tilde{v} = 0 \quad \text{if } p \geq k$$

$$(2.2) \quad \tilde{v} = k - \tilde{p} \quad \text{if } p < k,$$

where p is a realization of the random variable \tilde{p} .

The producer's utility is a strictly concave function defined over profit, that is $u = u(\pi)$ where π is given by (1). Thus, the individual is risk averse, but no other restrictions are placed on his/her preferences. The problem is to choose (y, x, z) to maximize expected utility; that is,

$$(3) \quad \max_{y,x,z} \mathcal{L} = E[u(\pi)],$$

where E denotes the mathematical expectation operator.

The first-order conditions (FOC) require $\mathcal{L}_y = \mathcal{L}_x = \mathcal{L}_z = 0$, where the subscripts to \mathcal{L} denote arguments of partial differentiation, that is,⁴

$$(4.1) \quad E[\tilde{u}'(\tilde{b} - c')] = 0$$

$$(4.2) \quad E[\tilde{u}'(f - \tilde{p})] = 0$$

$$(4.3) \quad E[\tilde{u}'(r - \tilde{v})] = 0,$$

where $\tilde{u}' = du/d\pi$, and $c' = dc/dy$.

To characterize the solution of these equations it is necessary to be specific about the relationship between local cash price and futures prices. Following Benninga, Eldor, and Zilcha, and others, the cash price is written as a linear function of the futures price:

$$(5) \quad \tilde{b} = \alpha + \beta\tilde{p} + \tilde{\theta},$$

where \tilde{p} and $\tilde{\theta}$ are independently distributed and $E(\tilde{\theta}) = 0$. Because of the definition in (2), equation (5) also uniquely defines the relationship between the terminal value of the put option and the cash price. Using (5), the FOC in (4) can be rewritten as

$$(6.1) \quad E[\tilde{u}'(\alpha + \beta f + \tilde{\theta} - c')] = 0$$

$$(6.2) \quad E[\tilde{u}'(f - \tilde{p})] = 0$$

$$(6.3) \quad E[\tilde{u}'(r - \tilde{v})] = 0,$$

where (6.1) uses (4.2) rewritten as $E[\tilde{u}'(\beta f - \beta\tilde{p})] = 0$.

The Case of Unbiased Prices

For any given utility function, the solution of equations (6) will depend crucially on the decision maker's perception of the futures price

² Input prices and the option premium are implicitly compounded to the end of the period using the (constant) market interest rate, so that all monetary variables in (1) are commensurable.

³ Because choosing a profit-maximizing level of inputs is equivalent to choosing a level of output when production is nonstochastic, in the production/hedging problem y is the decision variable of the producer. The effects of exogenous variables on the optimal input levels could be obtained using the (nonstochastic) conditional input demand functions implied by the cost function via the derivative property.

⁴ Because the utility function is strictly concave and the cost function is strictly convex in output, the second-order conditions are satisfied.

and option value distribution relative to the prices f and r . To account for this, it is convenient to define the notion of price bias.⁵

Specifically, if the producer's expectation of the end-of-period futures price equals the price of a futures contract, i.e., $\bar{p} \equiv E(\bar{p}) = f$, then the futures price is unbiased. Similarly, the expected (gross) return from the option position, $\bar{v} \equiv E(\bar{v})$, is

$$(7) \quad \bar{v} = \int_0^k (k - p) \psi(p) dp,$$

where $\psi(p)$ is the density function of the distribution of price as perceived by the producer. Following Black and Scholes, general equilibrium option pricing formulae assign a price to the option which, in our framework, is equivalent to the expected returns from the option (i.e., risk attitudes do not matter). Thus, the producer will perceive options to be fairly priced if $r = \bar{v}$, and in this case the option price is unbiased.

To analyze the solution, the strategy is first to consider the benchmark case of unbiased prices. The effects of biased prices are investigated in terms of comparative statics results from this benchmark. For unbiased prices ($\bar{p} = f$ and $\bar{v} = r$), and taking the nonrandom elements out of the expectation operator, the first-order conditions (6) can be rewritten as

$$(8.1) \quad \text{Cov}(\bar{u}', \bar{\theta})/E\bar{u}' = c' - \alpha - \beta f,$$

$$(8.2) \quad \text{Cov}(\bar{u}', \bar{p}) = 0,$$

$$(8.3) \quad \text{Cov}(\bar{u}', \bar{v}) = 0,$$

where $\text{Cov}(\cdot, \cdot)$ denotes the covariance operator.

Consider first the solution for the optimal futures and option positions for any given level of output, which is obtained by solving (8.2) and (8.3) for x and z conditional on y . Because of the dependence in (5) the random profit can be written as

$$(9) \quad \bar{\pi} = \pi_0 + \bar{\theta}y + \bar{p}[\beta y - x] - \bar{v}z,$$

where $\pi_0 = [\alpha y - c(y) + fx + rz]$ is the nonstochastic component of profit. Now consider $x = \beta y$ and $z = 0$ as a candidate solution. With these levels of hedging instruments, the only

randomness left in $\bar{\pi}$ and in \bar{u}' is due to $\bar{\theta}$. Because $\bar{\theta}$ and \bar{p} are by assumption independently distributed, then $\text{Cov}(\bar{u}', \bar{p}) = 0$ and $\text{Cov}(\bar{u}', \bar{v}) = 0$ so that $x^* = \beta y$ and $z^* = 0$ solve equations (8.2) and (8.3). Because the second-order conditions hold globally, this solution solves the expected utility-maximization problem.

Given this optimal choice of hedging instruments, equation (8.1) will solve for the optimal level of output y^* . Because in this case random profit reduces to $\bar{\pi} = (\alpha + \beta f + \bar{\theta})y - c(y)$, the choice of output level reduces to the standard problem of the competitive firm under output price uncertainty, where the random price is $(\alpha + \beta f + \bar{\theta})$. Using known results of this model, under risk aversion, production takes place at a point at which marginal cost is lower than the expected price (with optimal hedging), i.e., $c'(y^*) < \alpha + \beta f$, indicating that a portion of price risk resulting from the basis cannot be hedged away.

Because there is some residual uncertainty concerning the local cash price, the degree of risk aversion also influences optimal output. Specifically, the output level y^* is inversely related to the degree of risk aversion (Baron). Finally, a *ceteris paribus* increase in nondiversifiable basis uncertainty (a mean-preserving spread of $\bar{\theta}$) will in general decrease the optimal output level, a sufficient condition being that the Pratt measure of absolute risk aversion is decreasing in profit (Ishii). These conclusions are summarized in the following:

Result 1. When futures and options prices are unbiased and cash and futures prices are related as in (5), then (a) a fraction β of production is hedged in the futures market, (b) options are not used as hedging instruments, (c) and the portion of nondiversifiable basis risk affects the production level.

The absence of options from the optimal hedge may seem counterintuitive and warrants clarification. In the absence of futures and options positions, the risk faced by the producer depends upon the distribution of cash prices which, from (5), is assumed to be a linear function of the end-of-period futures price \bar{p} plus an orthogonal component $\bar{\theta}$. Neither the futures contract nor the put option can provide any hedge against the basis risk that is independent of \bar{p} . However, because the remaining hedgeable risk is linear in \bar{p} , it follows that a futures contract (which yields a pay-off that is also linear in \bar{p}) must provide a better hedge than an option contract (the pay-off of which is nonlinear in \bar{p}). Thus, in this context the option has no value as

⁵ This definition of bias illustrates the producer's beliefs about the price distribution and does not warrant any implication about market efficiency.

a hedging instrument if futures contracts are also present.⁶

The optimal hedge ratio for futures derived above, $x^*/y = \beta$, is the same as that derived under similar conditions for the case of futures only (Benninga, Eldor, and Zilcha; Kahl). This optimal hedge ratio satisfies the condition $\beta = \text{Cov}(\tilde{b}, \tilde{p})/\text{Var}(\tilde{p})$ and thus could be estimated by a linear regression of cash on futures prices.

Additional results for the general solution may be obtained under special conditions. First, if there is no orthogonal basis risk ($\tilde{\theta} \equiv 0$), then the FOC of equation (8.1) reduces to $c'(y^*) = \alpha + \beta f$. This means that the optimal output level is independent of the distribution of \tilde{p} , i.e., production and hedging/speculative decisions are separated. Second, when the basis ($\tilde{b} - \tilde{p}$) and the futures price \tilde{p} are independent (i.e., $\beta = 1$), the optimal hedge is the full hedge in the futures market, although in this case production and hedging decisions are not necessarily separated.

A separation result can also occur under our assumptions concerning basis risk if the utility function is of the CARA type. Assume a negative exponential utility function $\tilde{u} = -\exp(-A\tilde{\pi})$, where $A \equiv -u''/u'$ is the (constant) Pratt coefficient of absolute risk aversion, such that $\tilde{u}' = A \exp(-A\tilde{\pi})$. Because \tilde{p} and $\tilde{\theta}$ are independently distributed, it is verified that for CARA equation (6.1) can be written as

$$(10) \quad \frac{\int \theta \exp(-A\theta y) h(\theta) d\theta}{\int \exp(-A\theta y) h(\theta) d\theta} = c'(y) - \alpha - \beta f,$$

where $h(\theta)$ is the density function of $\tilde{\theta}$. Thus, the optimal output level y^* that solves equation (10) will not be affected by parameters of the distribution of \tilde{p} . This can be summarized in the following:

Result 2. If either (a) there is no basis uncertainty or (b) there is a CARA utility function and cash and futures prices are related as in (5), then there is separation between production and hedging (speculative) decisions.

This separation result means that, when the producer believes that the current futures price is a biased indicator of the end-of-period futures

price, it is more efficient for the producer to speculate on this disparity through portfolio decisions than through production decisions. This result with no basis uncertainty is essentially the same as those of Danthine; Holthausen; and Feder, Just, and Schimtz. The separation result with linear basis risk is illustrated by (10). The general case of (8.1) shows that, at the optimal output level, the marginal cost is less than the expected return from an optimally hedged position by an amount which reflects the risk premium of the unhedgeable risk [the left-hand-side of (8.1)]. As shown in (10), under CARA this risk premium is independent of that portion of price risk which is orthogonal to $\tilde{\theta}$, leading to separation between production and hedging decisions.

The Role of Expectations

Result 1 above describes the hedging decisions of a producer whose expectations agree with the market forecasts as displayed by the futures price and option premium. When this condition is relaxed, the optimal hedging rule $x^* = \beta y$ and $z^* = 0$ is modified. A convenient way to model the divergence of individual expectations from the market expectations, as aggregated in the futures price f and in the option price r , is to let f and r change while holding the producer's subjective distribution of \tilde{p} unchanged.⁷

Consider first hedging decisions conditional on the output level y . In this case equations (4.2) and (4.3) will solve for x^* and z^* . Totally differentiating these FOC and solving yields

$$(11) \quad \begin{bmatrix} dx \\ dz \end{bmatrix} = \frac{1}{\Delta} \begin{bmatrix} -\mathcal{L}_{zz} & \mathcal{L}_{zx} \\ \mathcal{L}_{xz} & -\mathcal{L}_{xx} \end{bmatrix} \cdot \begin{bmatrix} \mathcal{L}_{zf} & \mathcal{L}_{zr} \\ \mathcal{L}_{xf} & \mathcal{L}_{xr} \end{bmatrix} \begin{bmatrix} df \\ dr \end{bmatrix},$$

where

$$\mathcal{L}_{xx} = E[\tilde{u}''(f - \tilde{p})^2],$$

$$\mathcal{L}_{xz} = \mathcal{L}_{zx} = E[\tilde{u}''(r - \tilde{v})(f - \tilde{p})],$$

⁶ There are circumstances in which both futures and options may be useful hedging devices. In general, these cases will display a distribution of profit which is nonlinear in the random price. Examples of these situations may involve a nonlinear basis relationship or the presence of production risk which is not orthogonal to price risk. The characterization of these cases is left for further research.

⁷ This is consistent with the assumptions that f and r are exogenously given to the producer. Alternatively, one could hold the prices f and r constant and investigate how changes in the subjective distribution affect optimal hedging. Because the assumptions do not rule out distributions with more than two moments, this alternative may be impractical.

$$\mathcal{L}_{zz} = E[\tilde{u}''(r - \bar{v})^2],$$

$$\mathcal{L}_{xf} = E[\tilde{u}''(f - \bar{p})x] + E\tilde{u}',$$

$$\mathcal{L}_{xr} = E[\tilde{u}''(f - \bar{p})z],$$

$$\mathcal{L}_{zf} = E[\tilde{u}''(r - \bar{v})x],$$

$$\mathcal{L}_{zr} = E[\tilde{u}''(r - \bar{v})z] + E\tilde{u}', \text{ and}$$

$$\Delta = \mathcal{L}_{xx}\mathcal{L}_{zz} - (\mathcal{L}_{xz})^2.$$

Under CARA, and using the first-order conditions (4.2) and (4.3), it is verified that $\mathcal{L}_{xf} = \mathcal{L}_{zr} = E\tilde{u}'$ and $\mathcal{L}_{xr} = \mathcal{L}_{zf} = 0$. Under CARA, therefore, equation (11) reduces to

$$(12) \quad \begin{bmatrix} dx \\ dz \end{bmatrix} = \frac{E\tilde{u}'}{\Delta} \begin{bmatrix} -\mathcal{L}_{zz} & \mathcal{L}_{zx} \\ \mathcal{L}_{xz} & -\mathcal{L}_{xx} \end{bmatrix} \begin{bmatrix} df \\ dr \end{bmatrix}.$$

From the second-order conditions we know that $\mathcal{L}_{xx} < 0$, $\mathcal{L}_{zz} < 0$, and $\Delta > 0$. It can also be proved that under CARA $\mathcal{L}_{zx} = \mathcal{L}_{xz} > 0$.⁸ Hence, (12) yields:

Result 3. Under CARA, a *ceteris paribus* change in the futures price leads to a change in futures and options sold in the same direction, i.e., $\partial x^*/\partial f > 0$ and $\partial z^*/\partial f > 0$. A *ceteris paribus* change in the option premium leads to a change in futures and options sold in the same direction, i.e., $\partial x^*/\partial r > 0$ and $\partial z^*/\partial r > 0$.

The relative magnitude of the comparative statics effects also provides some insight on how futures and options are used to exploit information on futures and options bias. First, (12) implies that $\partial x^*/\partial r = \partial z^*/\partial f$ because $\mathcal{L}_{zx} = \mathcal{L}_{xz}$. Also, from (12) we obtain

$$(13) \quad dz - dx = (E\tilde{u}'/\Delta) [(\mathcal{L}_{zz} + \mathcal{L}_{xx})df - (\mathcal{L}_{zx} + \mathcal{L}_{xz})dr].$$

Under CARA $(\mathcal{L}_{zz} + \mathcal{L}_{xx}) > 0$ and $(\mathcal{L}_{zx} + \mathcal{L}_{xz}) < 0$.⁹ Thus we can conclude:

Result 4. Under CARA, a *ceteris paribus* change in futures or options price results in a larger change in the option position than in the futures position, with changes in r implying the largest changes. That is: $\partial z^*/\partial r > \partial x^*/\partial r = \partial z^*/\partial f > \partial x^*/\partial f > 0$.

The comparative statics of results 3 and 4 should be interpreted with care because they consider the effects of only r or f changing. When the producer differs from the market in terms of his/her perception of the dispersion of price but not in the expected value, only the option price

will be perceived as biased, and the comparative statics of a change in r applies. Thus, for example, if one started from the unbiased solution of the basic independence case $x^* = y$ and $z^* = 0$, then an increase in r (i.e., the market is overstating the volatility of \bar{p} from the individual point of view) would lead to a partly speculative futures open position $x^* > y$ such that more futures are sold. At the same time a position $z^* > 0$ in the option market is also open, such that some put options are also sold. Because the change in option position is larger than the change in the futures position by result 4, the resulting pay-off of the speculative position resembles a short straddle, a strategy which is deemed useful for speculating on beliefs about the volatility.¹⁰

Alternatively, changes in the producer's beliefs concerning expected price would bias both futures and option prices. If, at the same time, the producer perceives an offsetting change in the dispersion of price, then only the futures price may be perceived as biased. In this case the comparative statics of a change in f applies. However, this special case may not be very interesting; rather, one may want to know the effects of changing the futures price f when volatility is perceived unchanged. In this case the option premium must be allowed to change when the price of futures changes. A way of doing that would be to let $dr = \delta df$, where the coefficient δ is known as the "delta" of the option (Cox and Rubinstein), and to pursue the comparative statics analysis in terms of total derivatives. An alternative and more fruitful analysis involves reformulating the problem in terms of futures and straddles. This approach is pursued in the next section.

Speculative Hedging with Options

The analysis so far has shown little role for options as a hedging instrument. As long as the exogenous risk is linear in price, the futures market provides a perfect hedge. Moreover, the individual speculative decisions depend upon market prices (f and r) and his/her subjective beliefs concerning the "fair" value of these prices. If these prices are perceived as biased, then a speculative position which includes the use of options may occur.

⁸ Proof of this result is available from the authors upon request.

⁹ Proof of this result is available from the authors upon request.

¹⁰ A short straddle position is obtained by selling one futures and two put options, or equivalently by selling one put and one call options. See Cox and Rubinstein for more details on this and other strategies.

The results concerning speculative decisions are obscured because the futures and put contracts are partial substitutes (a futures equals a long call and a short put). As pointed out before, the bias in the futures price depends on expected price, while the bias in option premiums depends on both expected price and volatility. Thus, changes in price expectations have a direct impact on the expected return (or bias) of both instruments.

The analysis of speculative decisions can be sharpened if the individual speculates using futures contracts and straddles. A long (short) straddle is a combination of a long (short) call and a long (short) put at the same strike price. Because a synthetic call can be constructed using futures and puts, a straddle can also be constructed using futures and puts. Thus, recasting the analysis with this instrument does not entail a change in the choices available to the individual.

The main determinant of the straddle price is the volatility of the end-of-period futures price. From the individual perspective, changes in expectations concerning the futures price affect the bias in the futures but have little effect on the bias in the straddle, while changes in beliefs about the dispersion of price (volatility) affect only the bias in the straddle.

Because basis risk has been investigated earlier, the analysis is simplified by assuming no basis risk ($b \equiv \bar{p}$) and by concentrating on the speculative decisions given a (fully hedged) output level. To this end, let $q \equiv (y - x)$ denote the speculative (open) futures market position ($q > 0$ is long), s be the straddle position ($s > 0$ is a long straddle), t be the market price of a long straddle with strike price k (the premium of the put plus the premium of the call), and \bar{w} be the payoff of the straddle position. The profit defined in terms of open futures and straddle positions then is written as

$$(14) \quad \bar{\pi} = fy - c(y) + (\bar{p} - f)q + (\bar{w} - t)s.$$

The payoff of the straddle is given by the absolute value function,

$$(15) \quad \bar{w} = |\bar{p} - k|.$$

It is convenient to let $\bar{p} \equiv \bar{p} + \bar{e}$, where \bar{e} is a random variable with density function $g(e)$ and satisfying $E(\bar{e}) = 0$. Also, assume that the strike price is chosen equal to the expected price, so that $k = \bar{p}$ and $\bar{w} = |\bar{e}|$. If one maximizes the expected utility of profit as given in (14) conditional on the output level, the first-order conditions are

$$(16.1) \quad E[\bar{u}'(\bar{p} - f + \bar{e})] = 0, \text{ and}$$

$$(16.2) \quad E[\bar{u}'(|\bar{e}| - t)] = 0.$$

For the results that follow, assume that the individual perceives the price to be symmetrically distributed, i.e., $g(e) = g(-e)$. Then,

$$(17) \quad \int_{e < 0} F(e)g(e)de = \int_{e > 0} F(-e)g(e)de$$

for any function $F(e)$. For notational convenience, define¹¹

$$(18) \quad E^+[J(e)] \equiv 2 \int_{e > 0} J(e)g(e)de$$

for any function $J(e)$. Using this symmetry assumption, the FOCs can be expressed in terms of the realizations $e \geq 0$ only. In particular, equations (16) can be rewritten as

$$(19.1) \quad E^+[K(\bar{e})\bar{e}] + (\bar{p} - f)E^+[L(\bar{e})] = 0,$$

$$(19.2) \quad E^+[L(\bar{e})(\bar{e} - t)] = 0,$$

where $K(\bar{e}) \equiv [u'(\pi(\bar{e})) - u'(\pi(-\bar{e}))]$ and $L(\bar{e}) \equiv [u'(\pi(\bar{e})) + u'(\pi(-\bar{e}))]$.¹²

Note that $E^+[L(\bar{e})] > 0$ and, assuming risk aversion ($u'' < 0$), for $e > 0$:

$$(20) \quad K(e) \geq 0 \text{ as } q \leq 0.$$

Thus, if the futures price is unbiased ($\bar{p} = f$) then $q^* = 0$ for (19.1) to hold. If $\bar{p} > f$, then (19.1) requires $E^+[K(\bar{e})\bar{e}] < 0$, which implies $q^* > 0$ in view of (20). Similarly, if $\bar{p} < f$, then $E^+[K(\bar{e})\bar{e}] > 0$, which requires $q^* < 0$. This can be summarized as follows:

Result 5. Under risk aversion and with a symmetric distribution of price, the qualitative optimal speculative futures position depends only upon the bias in the futures price; i.e., $q^* \geq 0$ as $\bar{p} \geq f$. In particular, this speculative futures position is independent of the bias in the straddle price.

The reformulation of the asset mix in terms of futures and straddles allows a clearer representation of how changes in expected price or implied volatility affect optimal speculative de-

¹¹ The normalization factor 2 in (18) is the reciprocal of the probability of positive realizations of \bar{e} (which is 0.5 because of the symmetry assumption), so that E^+ is properly interpreted as an expected value.

¹² $u'(\pi(\bar{e}))$ denotes the marginal utility evaluated at the profit level associated with a realization of the random variable \bar{e} , while $u'(\pi(-\bar{e}))$ denotes the marginal utility evaluated at the profit level associated with the negative of the same realization of the random variable \bar{e} .

cisions. This reformulation also clarifies the comparative statics of results 3 and 4. For example, a perceived decline in the dispersion of \bar{p} means that the producer/speculator views both puts and calls as overpriced and hence wishes to sell both, i.e., sell a straddle. If the problem is formulated in terms of futures and puts, then the sale of a (synthetic) straddle can be achieved by selling one futures and two puts. Thus, the use of futures to speculate on the dispersion of price emerging from result 3 is purely a function of constructing a straddle position.

The first part of this paper showed that options are not useful in hedging exogenous price risk, at least under the assumption of linear price risk. With the reformulation of the model using the straddle, however, we can show that options are desirable instruments to hedge the risk assumed by the agent because of an open speculative position in futures. For example, if the agent has a long futures position, then profit (and utility) will be low when p is low. In this situation, a long straddle that raises income in these states may be desirable. The same argument indicates that a long straddle may be useful when the agent chooses to short the futures contract.

Specifically, the FOC (19.1) determines the sign of q^* , which depends on the perceived bias in the futures price. The sign of s^* then is based on the remaining FOC (19.2). If the straddle is unbiased, then $\bar{w} = t$ where $\bar{w} \equiv E(\bar{w}) = E[\bar{e}] = E^+[\bar{e}]$, the last equality following from the symmetry assumption. Thus, the FOC (19.2) can be rewritten as $E^+\{[L(\bar{e}) - L(\bar{w})](\bar{e} - \bar{w})\} = 0$, where $L(\bar{w})$ denotes the value of $L(e)$ at $e = \bar{w}$. Now, $L(e)$ is an increasing function of e at $s = 0$ if we assume $u''' > 0$ (as implied by non-increasing absolute risk aversion) because $dL/de = [u''(\bar{e}) - u''(-\bar{e})]q$ at $s = 0$, and $d^2L/de^2 = [u'''(\bar{e}) + u'''(-\bar{e})]q^2 > 0$ for $q \neq 0$. Thus, $\text{sgn}[L(\bar{e}) - L(\bar{w})] = \text{sgn}[\bar{e} - \bar{w}]$, so that the integrand in (19.2) is positive for all $e \neq \bar{w}$ and equal to zero at $e = \bar{w}$. Hence, with an unbiased straddle price at $s = 0$ the FOC in (19.2) is positive. Given the second-order conditions, s^* must also be positive for (19.2) to vanish.

For an unbiased straddle price, the long straddle position will not fully offset the open futures position. To see this note that, from (19.2), $E^+[L(\bar{e})(\bar{e} - t)] = \text{Cov}^+[L(\bar{e}), (\bar{e} - t)] = 0$ because $E^-(\bar{e} - t) = 0$. From the definition of $L(e)$, $dL/de = u''(\bar{e})(s + q) + u''(-\bar{e})(s - q)$. Because $L(e)$ cannot be monotonic in e (if this were the case then $\text{Cov}^+[L(\bar{e}), (\bar{e} - t)] \neq 0$), it follows that $(s + q)$ and $(s - q)$ must have opposite sign. Thus, $(s + q)(s - q) = s^2 - q^2 < 0$, which

implies $|s| < |q|$. For example, if $\bar{p} > f$, then $q^* > s^* > 0$, so that the resulting position is not equivalent to simply being a long call.

The analysis above has shown that a long straddle provides insurance against adverse outcomes induced by the open futures position. This conclusion is summarized in the following:

Result 6. Under nonincreasing absolute risk aversion, and with unbiased straddle price and a symmetric distribution of the spot price, the optimal straddle position will always be long when there is an open speculative futures position (either long or short); also, the straddle position will always be smaller than the open futures position, i.e. $0 < s^* < |q^*|$.

Results 5 and 6 together imply that the speculative position induced by a perceived bias in the futures price will have a nonlinear payoff whose shape is intermediate between that generated by only puts or calls and that generated by futures only. This nonlinear payoff will generate a positively skewed profit distribution even if the price distribution is symmetric. Indeed, the condition of nonincreasing risk aversion (or more generally $u''' > 0$) used above is equivalent to assuming a preference for positive skewness (Tsiang).

Note, however, that preference for skewness is not sufficient to justify using only puts or calls to generate a nonlinear payoff. For example, if the agent's expectation of the end-of-period futures price is higher than f but he/she agrees with the implied price volatility of the market, a viable speculative action would seem to involve buying call options. However, if the agent views the call as underpriced, he/she must simultaneously view the put as overpriced. Hence, buying a call and selling a put, i.e., buying futures, is a superior speculative device. Options in a pure sense (straddle) are used only to hedge the risk assumed by this open position.

Comparative statics results concerning the impact of changes in futures and option prices on the optimal portfolio of the individual can be obtained for a CARA utility function. Totally differentiating (16), using the FOC and the constant coefficient of absolute risk aversion $A \equiv -u''/u'$, and solving yields

$$(21) \quad \begin{bmatrix} dq \\ ds \end{bmatrix} = \frac{Eu'}{\Delta} \begin{bmatrix} \mathcal{L}_{ss} & -\mathcal{L}_{qs} \\ -\mathcal{L}_{qs} & \mathcal{L}_{qq} \end{bmatrix} \begin{bmatrix} df \\ dt \end{bmatrix},$$

where \mathcal{L}_{ij} are the elements of the Hessian matrix for the maximization problem, and hence $\mathcal{L}_{qq} < 0$, $\mathcal{L}_{ss} < 0$, and $\Delta = [\mathcal{L}_{qq} \mathcal{L}_{ss} - (\mathcal{L}_{qs})^2] > 0$. Furthermore, with the assumption of symmetry

in $g(e)$, $\mathcal{L}_{qs} \geq 0$ as $q \geq 0$.¹³ Hence: $\partial q^*/\partial f < 0$, $\partial s^*/\partial t < 0$, and $\partial q^*/\partial t = \partial s^*/\partial f \geq 0$ as $q^* \leq 0$. This can be summarized in the following:

Result 7. Under CARA and with symmetrically distributed prices, a *ceteris paribus* decrease in the current futures price will lead to an increase in the net long futures position; the net long straddle position will increase (decrease) if the net futures position is long (short). Similarly, a *ceteris paribus* decrease in the straddle price will increase the net long straddle position; the net long futures position will increase (decrease) if the agent is long (short) in open futures.

In the model reformulated in terms of open futures and straddles, the comparative statics of a change in futures price with the straddle premium held constant illustrate the adjustments when the producer differs from the market in terms of his/her perception of the expected price but not on the price volatility. This allows us to resolve the ambiguity arising from results 3 and 4. Because of our centering $k = \bar{p}$ and of the assumption of symmetry in the distribution of \bar{p} , a *ceteris paribus* change in f will not affect the straddle price t (although the price of puts and calls will be affected through their delta). In this light, the own-price effects on the demand for futures of result 7 are intuitively appealing. For example, starting at the unbiased solution $q^* = s^* = 0$, a decrease in f other things being equal (i.e., an increase in the agent's expected price relative to the market) leads to a net long position.

Similarly, the comparative statics of a change in t with f held constant illustrates the adjustments when the producer differs from the market in terms of his/her perception of the volatility of price but not on the expected price. For example, a *ceteris paribus* decrease of the straddle price t is equivalent to the producer perceiving an increase in the volatility of the futures price \bar{p} relative to the market. If one evaluates the comparative statics effects at the unbiased point $q^* = s^* = 0$, the own-price effect of straddle demand implies a movement toward a long straddle, a strategy that is useful when the market is understating the volatility of \bar{p} .

The cross-price effects can be understood by considering the underlying use of straddles as hedging instruments to offset the futures position. Thus, in the case of a decrease in f , the

agent will change his/her straddle position to hedge against the net change in futures position. For $q > 0$, this means an increase in s . For $q < 0$, this means that the absolute value of q decreases so that fewer straddles are needed to hedge the position.

Pitfalls of Mean-Variance Analysis

The introduction pointed out that the truncation and nonlinearity introduced by options leads to a violation of commonly used justifications for mean-variance analysis. The results of the preceding section gives us an opportunity to illustrate this point further. Consider a mean-variance formulation of this model. For the profit equation (14) we have

$$(22.1)$$

$$E(\tilde{\pi}) = fy - c(y) + (\bar{p} - f)q + (\bar{w} - t)s, \text{ and}$$

$$(22.2) \quad \text{Var}(\tilde{\pi}) = q^2 \text{Var}(\tilde{e}) + s^2 \text{Var}(|\tilde{e}|)$$

because $\text{Cov}(\tilde{e}, |\tilde{e}|) = 0$ due to the assumed symmetry in $g(e)$.

Maximizing any function that is increasing in $E(\tilde{\pi})$ and decreasing in $\text{Var}(\tilde{\pi})$, as given in (22), would imply $s^* = 0$ for $\bar{w} = t$. Hence, in the mean-variance framework the optimal straddle position is zero if the straddle price is unbiased, regardless of the optimal position in the futures. This conclusion contrasts sharply with the results of the previous section. Because the distribution of profit cannot be normal in the presence of options, the ultimate rationale for mean-variance analysis must hinge on the undesirable assumption of quadratic utility.¹⁴

Conclusions

In this paper, we have analyzed the production and hedging decisions of the competitive firm facing both futures and options markets within an expected utility model that allows for basis risk. When futures prices and options premiums are perceived as unbiased, options are redundant hedging instruments. The optimal hedging strategy involves using only futures, and the amount of futures is determined by the covariance of cash and futures prices. However, if futures prices and/or options premiums are perceived as biased,

¹³ Proof of this result is available from the authors upon request.

¹⁴ Note that this utility function displays increasing absolute risk aversion with $u''' = 0$, which violates the conditions used to derive result 6 and rules out preference for positive skewness.

options are typically used along with futures. Thus, in this model options are appealing more as speculative tools to exploit private information on the price distribution, and less so as an alternative hedging instrument.

The qualitative effects of biased prices on the use of options and futures was investigated in terms of comparative statics effects. The nature of the speculative activity brought about by biased prices is clarified if the problem is formulated in terms of open futures and straddle positions. The sign of the open position in the futures depends only on the bias in the futures price, and (long) straddles are used even if the straddle price is unbiased whenever the futures position is open. In this context, options emerge as a useful device to insure against the price risk in an open speculative position.

Dynamically Optimal After-Tax Grain Storage, Cash Grain Sale, and Hedging Strategies

Russell Tronstad and C. Robert Taylor

This article utilizes a stochastic dynamic programming (SDP) model that considers the state variables of (a) before-tax income, (b) grain storage, (c) quantity of futures position, (d) value of futures position, (e) wheat price, and (f) basis level. Decision variables are monthly cash grain sales and futures market transactions. In comparing the post-sample performance of SDP to other marketing strategies over a four-year period, SDP resulted in \$5,961 to \$25,021 more wealth than the other strategies considered. Also, these other strategies yielded a standard deviation of after-tax income that was 30% to 621% greater than that from the SDP framework.

Key words: before-tax income, certainty equivalence, marketing strategies, stochastic dynamic programming.

Many studies have examined the optimal amount of grain that producers should sell or hedge via cash and futures markets under varying assumptions of market position, futures and cash price determination, unbiasedness of futures prices, production, utility function, and risk aversion (e.g., Berck, Heifner, Johnson, Kahl, Karp, Peck, Rolfo, Ward and Fletcher). However, these studies have failed to recognize many factors faced by producers in marketing grain. For example, producers will have different income levels and thus income tax rates as the price of grain varies. Thus, under a cash accounting system, the current income of producers will affect whether they should store grain into the next tax period, sell in the futures market, or sell in the cash market. In analyzing the effects of the 1986 Tax Reform Act on optimal cash grain marketing decisions, Tronstad and Taylor (1989b) solved for dynamically optimal after-tax marketing decisions utilizing a stochastic dynamic programming (SDP) model. They found that the sensitivity of optimal cash grain sales to income tax considerations could be magnified by the 1986 Tax Reform Act (TRA) because of larger jumps in marginal tax rate schedules. Thus, income tax considerations are likely important in determining optimal hedging decisions, even though the

1986 TRA decreased the marginal tax rate for most individuals. Also, the effects of government programs are not incorporated into the optimal hedging decisions of the above studies, and most grain producers participate in government programs.

The purposes of this study are to (a) extend the after-tax cash grain-marketing model of Tronstad and Taylor (1989b) to include after-tax hedging decisions; and (b) explore the benefits of an optimal dynamic marketing decision rule for grain producers which incorporates the discrete aspects of hedging decisions (i.e., progressive income tax structure and lumpiness of futures contracts), the before-tax income level of grain producers, the stochastic nature of cash price and basis levels without assuming certainty equivalence (i.e., with respect to the nonlinearities of the tax function), and government payments. As in Tronstad and Taylor (1989b), a representative Montana winter wheat producer was used to illustrate how these factors affect grain-marketing decisions and firm profitability because a much simpler model formulation results for a Montana grain producer than a grain producer from a multiple-crop region. That is, as a result of moisture limitations, Montana dryland grain producers essentially have only winter wheat as an economically viable crop alternative. However, the single-crop model can give insight into optimal decisions for a multiple-crop producer because the focus is on method and

Russell Tronstad is an extension economist, University of Arizona; C. Robert Taylor is Alfa Professor of Agricultural Policy, Auburn University.

timing of grain sales rather than crop selection. Forward contracting and options are not considered because futures contracts are similar to forward contracting and the minimum selling price concept of options is partially captured by government loan and target prices. As in Tronstad and Taylor (1989b), optimal grain-marketing decisions are obtained for a multiperiod horizon where the producer is presumed to maximize expected wealth.

Two commonly utilized frameworks which incorporate time and uncertainty in decision problems are SDP and Ito's stochastic control theory. SDP is selected for this analysis because (a) the discreteness of income tax schedules and futures contracts is more amenable to an SDP than stochastic control theory formulation, (b) an explicit solution is often not achieved for many problems when using optimal control theory (Burt), and (c) direct enumeration techniques are the only alternative to SDP and these methods are computationally inefficient (Bellman).

The next section presents the SDP formulation of the grain-marketing model. Cash price and basis transition probabilities are discussed in the third section; marginal tax schedules and other critical features are delineated in the fourth section.¹ The fifth section presents slices of the optimal grain-marketing decision rule generated from the SDP model. Then, the post-sample performance of the SDP marketing approach is

compared to other cash and futures marketing strategies from August 1985 to January 1989. Finally, the usefulness of an SDP approach is discussed.

Stochastic Dynamic Programming Model

To keep the SDP model formulation manageable, only March futures contracts are considered. The fact that winter wheat is a storable commodity makes this restriction reasonable because market conditions which affect old (new) crop futures contracts will usually affect all other old (new) crop futures contracts in a similar manner. However, even if an inverse market exists across adjacent futures contract months, immediate cash sales would likely be preferred to selling in the futures market. Thus, any benefit from adding another futures horizon is probably quite small. March futures contracts are utilized so the producer will be allowed to (a) hedge grain into the next tax year, (b) hedge anticipated production before the main growing season of winter wheat, and (c) receive almost all of the carrying charge of storage from hedging before the new U.S. harvest begins, as illustrated by Working.

The decision maker is assumed to maximize the expected present value of after-tax wealth over a multiyear planning horizon subject to the state variables of monthly cash price, basis, before-tax income, grain storage, futures position, and value of March futures position. Formulation of this problem as a SDP model results in the following recursive equation:

¹ Basis is defined as futures minus the cash price in this analysis. This definition is frequently found in academic literature, whereas the trade literature usually defines basis as cash minus the futures price.

$$\begin{aligned}
 (1) \quad & V_t(P_t, B_t, I_t, ST_t, QM_t, VM_t) = \underset{XC_t, XM_t}{\text{MAX}} E\{T[R(P_t, B_t, I_t, ST_t, QM_t, VM_t)] \\
 & \quad + \beta \cdot V_{t+1}(P_{t+1}, B_{t+1}, I_{t+1}, ST_{t+1}, QM_{t+1}, VM_{t+1})\} \\
 & \text{subject to} \\
 (2) \quad & I_{t+1} = I_t + P_t \cdot XC_t + VI_t + DEF_t - C_t \\
 (3) \quad & I_t = 0; \text{ if } t = 1, 13, 25, \dots \\
 & \quad \text{or the month of January} \\
 (4) \quad & 0 \leq XC_t \leq ST_t + Q_t \\
 (5) \quad & 0 \leq ST_t \leq SC \\
 (6) \quad & ST_{t+1} = ST_t + Q_t - XC_t \\
 (7) \quad & QM_{t+1} = QM_t + XM_t \\
 (8) \quad & -XM_t = QM_t; \text{ if } t = 3, 15, 27, \dots, \\
 & \quad \text{or the month of March}
 \end{aligned}$$

where t is the monthly index; $V_t(\cdot)$ is the maximum expected present value of after-tax income from month t through the multiyear terminal month T given the initial state; P_t is the mid-month price of Montana winter wheat; B_t is the mid-month Kansas City Board of Trade (KCBT) March futures price minus P_t ; I_t is the beginning before-tax income state of the producer in month t ; ST_t is the beginning storage state of the grain producer in month t ; QM_t is the beginning quantity of March futures position (a positive value indicates a short position); VM_t is the beginning value of March futures position (average transaction price (ATP_t) of a short futures position multiplied by the quantity short); XC_t is cash winter wheat sales; XM_t is March futures transactions [positive (negative) values denote selling (buying) of March futures contracts]; E is the expectation operator; $T\{R(\cdot)\}$ is after-tax income as a function of before-tax revenue, $R(\cdot)$; β is the real discount factor ($1/1.005$); Q_t is production for month t (nonzero only for the month of August); SC is total storage capacity; AQ_t is anticipated production (positive for the months of April through August); VI_t is the profit or loss generated from closing out a short futures position; DEF_t is deficiency payments; C_t is production, commission and margin expenses; $f_i(\cdot)$'s ($i = 1, 2$) are stochastic Markovian relationships with associated random variable e_{it} 's.

Before-tax income (I_t), cash grain sale (XC_t), storage (ST_t), and price (P_t) constraints in equations (2) through (6) and (13) are quite similar to, and the only constraints necessary for, an SDP model that considers cash grain sales alone as solved by Tronstad and Taylor (1989b). However, the primary difference occurs when before-tax income gained or lost from hedging (i.e., VI_t , commission and/or margin expenses) enters constraint (2). Hedging and basis level

constraints [i.e., equations (7)–(12) and (14)] influence VI_t and C_t in equation (2) indirectly.

I_t , ST_t , QM_t , and VM_t are deterministic state variables in the above formulation. Because of uncertainty associated with cash price (P_t) and basis (B_t) movements, P_t and B_t are treated as stochastic state variables. Even though P_t and B_t enter the before-tax function [$R(\cdot)$] linearly, certainty equivalence requirements are not satisfied for P_t or B_t because the after-tax function [$T\{\cdot\}$] is nonlinear (Simon, Theil). Subsequently, P_t and B_t must be treated as true stochastic state variables in the SDP model formulation.

Except for January, ending before-tax income (I_{t+1}) for each period is before-tax income carried over from the previous month (I_t) plus current cash grain sale receipts ($P_t \cdot XC_t$), hedging profits (positive VI_t), and deficiency payments (DEF_t); minus current costs of production, commission and margin expenses (C_t), and hedging losses incurred in month t . The producer is assumed to comply with government program requirements, as is the case for virtually all Montana dry-land grain producers. I_t begins each tax year (i.e., January) with zero before-tax income (constraint 3) because grain sales, profits or losses on hedging, deficiency payments, and before-tax income accumulated prior to January are accounted for by taxable income calculated in December of the previous year. Ending storage for month t (ST_{t+1}) is increased by grain harvested during August (Q_t) and decreased by cash grain sales (XC_t) as given in equation (6).

The ending month's quantity of March futures position (QM_{t+1}) is increased by selling March futures contracts (i.e., positive XM_t) and decreased by buying March futures contracts (i.e., negative XM_t). If a March futures position exists (i.e., $QM_t > 0$) at maturity, the futures position must be closed as indicated in equation (8). Equations (9) and (10), called legitimate hedg-

ing constraints, allow the producer to maintain a bona fide IRS hedging account. That is, the producer cannot have a long futures position ($0 \leq QM_t$) or a short futures position that is greater than current storage plus anticipated production ($QM_t \leq ST_t + AQ_t$) or storage capacity ($0 \leq QM_t \leq SC$). This constraint also implies that current futures transactions (XM_t) are bound between the negative of any current futures position ($-QM_t$) and grain in storage plus anticipated production minus any futures position ($ST_t + AQ_t - QM_t$). As indicated in (11), the ending monthly value of March futures contracts (VM_{t+1}) increases or decreases as a result of March futures transactions by the amount of $XM_t \cdot (P_t + B_t)$. Also, to maintain the original transaction price of March futures contracts sold when part

temporaneous basis because it should capture most of the information about recent transportation and market conditions between KCBT March futures price and P_t . Lagged cash prices are hypothesized to positively influence the basis because of increased storage costs. Maturity time influences the basis because storage costs are directly related to the length of time between the current month and the contract month. A negative time trend for the basis is anticipated because the Portland market has been stronger than the Gulf market in recent years.

Utilizing Schwarz's Bayesian information criteria (BIC)² (Schwarz) to determine appropriate lag lengths and variables, the following cash price and basis relationships were estimated (t -values are in parentheses):

$$\begin{aligned}
 (15) \quad P_t &= .4547 + .8960 \cdot P_{t-1} - .07815 \cdot HD_t \\
 &\quad (2.900) \quad (24.417) \quad (-2.406) \\
 &\quad - .00094026 \cdot MT_t + e_{1t} \quad \bar{R}^2 = .8982 \quad DH = -.1852 \\
 &\quad \quad \quad (-1.945) \\
 (16) \quad B_t &= .6185 \cdot B_{t-1} + .2548 \cdot B_{t-2} + .01359 \cdot TM_t + e_{2t} \quad \bar{R}^2 = .7906 \quad DH = -1.1848 \\
 &\quad (6.8753) \quad (3.0369) \quad (2.7761)
 \end{aligned}$$

of a short futures position is closed out, a profit (loss) of VI_t is subtracted (added) from (to) the amount associated with closing out part or all of a short futures position.

Cash Price and Basis Transition Probabilities

As in Tronstad and Taylor (1989b), Markovian transition probabilities for cash price were determined by estimating P_t as a function of own lagged price ($P_{t-j}; j = 1, 2, 3$), a harvest dummy variable (i.e., 1 for the months of June, July, and August; 0 otherwise), a time trend, and autoregressive error ($e_{t-j}; j = 1, 2, 3$). Lagged prices capture current grain market conditions. A harvest dummy variable for the months of June, July, and August captures any dampening effect on P_t of the harvest of hard red winter wheat. A time trend variable represents changes in P_t resulting from technological advances (e.g., new crop varieties, herbicides, and pesticides, in conjunction with no-till farming practices).

Markovian basis relationships were determined by estimating basis as a function of lagged basis ($B_{t-j}; j = 1, 2, 3$), lagged cash price levels ($P_{t-j}; j = 1, 2, 3$), time of basis to maturity (i.e., 0 to 11 months), and a time trend variable. Own-lagged basis is hypothesized to influence con-

where P_t is the mid-month Montana winter wheat price (\$/bu.) (*Agricultural Prices*), HD_t is a harvest dummy variable, MT_t is a monthly time trend, B_t is the basis level or mid-month KCBT March Futures (*Wall Street Journal*) minus P_t , TM_t is the number of months until maturity, e_{it} ($i = 1, 2$) is a normally distributed error term with a constant variance, \bar{R}^2 is the adjusted coefficient of determination, and DH is Durbin's H -statistic. The monthly data series runs from January 1977 to August 1988 and all prices are deflated by the index of prices paid by farmers (*Agricultural Prices*), utilizing August 1988 as a base period. Also, to reduce model complexity, the second-order Markov process of B_t in equation (16) was reduced to a first-order Markov process as described in Burt and Taylor.

Marginal Tax Schedules and Other Critical Input Features

The 1988 federal income tax code has three marginal tax rates. Marginal tax rates for married individuals filing jointly are 15% for tax-

² $BIC(j)$ chooses the j th model such that $2\ln(M_j) - k\ln(n)$ is largest, where M is the maximum likelihood function, k is the number of parameters associated with the j th model, and n is the number of observations.

able incomes less than \$29,750, 28% for taxable income between \$29,750 and \$71,901, 33% for taxable income between \$71,901 and \$171,090, and 28% for taxable income exceeding \$171,090. Standard deductions for a married couple (i.e., \$5,000) and two personal exemptions (i.e., \$3,900) are claimed in determining federal income tax liabilities.

State taxes for Montana are made up of ten relatively flat marginal tax brackets. After a \$4,280 standard deduction, the marginal tax rate is 2% for income less than \$1,400, 3% for income between \$1,400 and \$2,900, 4% for income between \$2,900 and \$5,700, 5% for income between \$5,700 and \$8,600, 6% for income between \$8,600 and \$11,400, 7% for income between \$11,400 and \$14,300, 8% for income between \$14,300 and \$20,000, 9% for income between \$20,000 and \$28,000, 10% for income between \$28,600 and \$50,000, and 11% for income greater than \$50,000. Also, social security taxes are included at a rate of 13.02% of income, with a maximum social security tax of \$5,702.80.

Grid dimensions utilized in this analysis are as follows; eight cash price (P_t) states (\$2.25, \$2.50, \$2.75, \$3.00, \$3.25, \$3.50, \$4.25, and \$5.00 per bushel); seven basis (B_t) states (-\$.75, -\$.15, \$.10, \$.35, \$.60, \$.85, and \$1.45 per bushel); seven income (I_t) states (-\$60,000 to \$60,000 in \$20,000 increments); nine storage (ST_t) states (0 bu. to 40,000 bu. in 5,000 bu. increments); nine quantity of March futures (QM_t) states (0 bu. to 40,000 bu. in 5,000 bu. increments); and eleven value of March futures (VM_t) states (\$1.50/bu. to \$6.50/bu. in \$.50 increments, multiplied by QM_t). The lower range of the state space for P_t (\$2.25/bu.) is essentially the current CCC loan rate of \$2.21 per bushel (\$2.28 in 1987). The distribution of P_t is somewhat skewed toward higher prices because of the CCC loan rate. Therefore, to reduce computation requirements, the upper end of the distribution of P_t is given a coarser grid space. Because the distribution of B_t is essentially symmetric, both tails of the distribution of B_t are given a coarser grid space.

The mid-point between each cash price and basis state increment is utilized in conjunction with equations (15) and (16) in calculating Markovian transition probabilities. For example, if the current cash price state is \$3.00 per bushel, equation (15) is utilized to determine an expected price for $t + 1$ in t so that the probability of cash going to a price state of \$3.25 per bushel was determined by integrating the area of cash

price falling between \$3.375 per bushel and \$3.125 per bushel in period $t + 1$, given that the error structure of equation (15) is normally distributed. This process was done for all cash price and basis states so that the product of the two probability matrices for each period would sum to one in going from one $\{P_t, B_t\}$ state combination to all possible $\{P_{t+1}, B_{t+1}\}$ combinations. These transition probabilities are utilized to calculate optimal expected values from one period to the next [i.e., $V_t(\cdot)$ from $V_{t+1}(\cdot)$] and determine an optimal converged decision rule. The reader is referred to Howard's book, *Dynamic Programming and Markov Processes*, for a more thorough discussion of this process.

Because before-tax income is always zero at the beginning of every tax year, -\$60,000 is about the lower limit of before-tax income that the firm could attain by the end of the tax year given production expenses, even if zero cash grain sales occurred. Conversely, with production expenses and "normal" production levels, the firm is unlikely to achieve a before-tax income level above \$60,000. Thus, I_t was discretized in increments of \$20,000 from -\$60,000 to \$60,000. ST_t , QM_t , XC_t , and XM_t were discretized in increments of 5,000 bushels because KCBT futures contracts are traded in 5,000 bushel increments.

The above state space adequately represents the state space of the producer, in that the unconditional probability of values occurring outside the state space is small. Discretization of continuous state variables is based on a subjective trade-off between computation requirements and sensitivity of the optimal decision rule to changes in the level of state variables. However, to minimize any bias associated with discretization of continuous state variables, linear interpolation of the optimal value function [i.e., values of V_{t+1} in the right-hand side of equation (1)] was utilized whenever the resulting state values in $t + 1$ did not exactly match the state space described above.

Critical production characteristics for this representative firm are farm payment acreage and crop production acreage of 1,000 acres; variable per acre production costs incurred in May (spraying), August (harvest), and September (planting) of \$6, \$6, and \$36.32, respectively; overhead costs of \$35,800/12 are charged for each month; and storage capacity (SC) of 40,000 bushels. Production costs are primarily based on Economic Research Service production costs for hard red winter wheat in the Northern Plains. Commission costs of \$37.50 are incurred for each

one-way trade of a 5,000 bushel futures contract. An initial margin of \$1,500 is required for each futures contract. Margin money requirements increase or decrease with futures price movements in order to maintain the initial margin cushion of \$1,500 per contract, or \$.30 per bushel. Thus, the margin expense or revenue incurred each month is the interest paid (0.5% each month) on the net balance in the producer's margin account. Other than the margin expense or revenue realized each month, the loss or profit on futures price movements does not accrue to before-tax income until a futures position is closed out.

Yield is estimated as a function of a time trend using annual Montana winter wheat yields from 1962 to 1987 (period of available data). Because 1985 was an unusually dry year compared to the other years in this period, a dummy variable was included for 1985. The following equation was estimated for Montana winter wheat yields (*t*-values are given in parentheses)

$$(17) \quad Y_t = 26.985 + .2361 \cdot AT_t - 16.42 \cdot D85, \\ (19.437) \quad (2.460) \quad (-4.646) \\ \bar{R}^2 = .472 \quad D-W = 1.533,$$

where Y_t is yield (bu./acre) (*Crop Production*), AT_t is an annual time trend variable (1962 = 1), $D85$ is a dummy variable for 1985 (1 if 1985, 0 otherwise), \bar{R}^2 is the adjusted coefficient of determination, and $D-W$ is the Durbin-Watson statistic. Y_t is utilized to determine production (Q_t) and anticipated production (AQ_t) in the SDP model formulation. Thus, both Q_t and AQ_t are simply Y_t multiplied by 1,000 acres.

Deficiency payments are distributed equally throughout the year as follows:

$$(18) \quad DEF_t = (TP_t - P_t) \cdot FPP/12; \\ \text{if } P_t < TP_t, \text{ else} \\ DEF_t = 0$$

where DEF_t is the deficiency payment received by the producer, TP_t is the target price (\$4.38, \$4.23, \$4.10, and \$4.00, prior to 1987, 1988, 1989, 1990 and beyond crop marketing years, respectively), and FPP is farm program production, set at 30,000 bushels. Equation (18) is a proxy to actual deficiency payments because P_t is used to approximate the average national winter wheat price. Also, caution should be exercised in using DEF_t when prices are above and below TP_t for the crop marketing year because the actual annual payment would be somewhat less than the cumulative monthly payment in (18).

Montana has a relatively dry and cool climate, and the loss in grain weight from reduced moisture content and/or spoilage is considered negligible. Also, the only cost associated with on-farm grain storage in this analysis is the time value of money associated with grain storage. Commercial grain storage was not considered.

Inventory financing costs of storage are captured in the SDP model through the discount factor. Even though the nominal interest rate for borrowed funds is undoubtedly greater than it would be for loanable funds, the after-tax differential in real terms is probably quite small. Also, off-farm income, additional enterprises, and income tax management tools other than grain storage are not considered.

Optimal Cash Grain Sale, Storage, and Hedging Decisions

This section graphically presents optimal grain-marketing decisions derived from the SDP model. Optimal grain-marketing decisions are presented for April and December to illustrate the converged optimal grain-marketing decision rule generated for every month and state.³ April illustrates hedging decisions in relation to anticipated production, and December illustrates the effects of income tax considerations on optimal cash grain sale and futures transactions.⁴

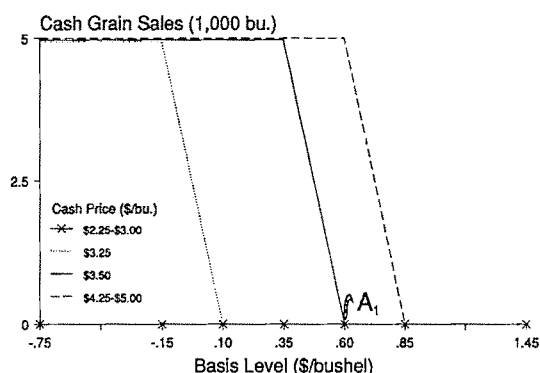

Figure 1 presents optimal marketing decisions for April where the state variables of cash price, basis, and storage vary. Because any short futures position (QM_t) in March must be closed, April always begins with no futures position. Thus, QM_t equals zero in figure 1, and QM_t equal to zero also implies that VM_t equals zero. The state variable of before-tax income (I_t) is also fixed at \$0.00 in figure 1 because income tax effects are less pronounced early in the tax year compared to months later in the tax year.

In interpreting figure 1, legend lines of cash price in conjunction with the basis level given on the horizontal axis determine the optimal level of cash grain sales and futures transactions. For example, if the current levels of cash price (P_t),

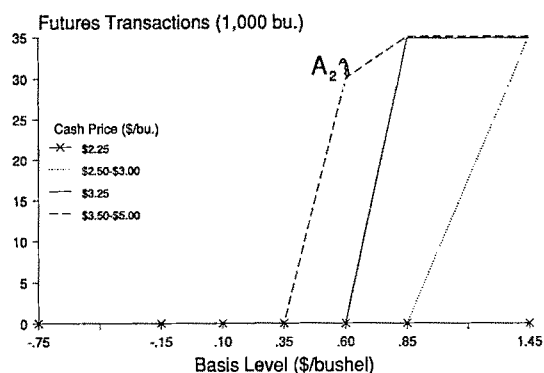

³ Convergence of the decision rule was obtained in 60 states, or 5 years.

⁴ Marketing decisions for additional months and scenarios are available from the authors upon request. Computation requirements for the model were 166 minutes of CPU time on a CRAY X/MP-48, or about 100 times greater than the computation requirements for just a cash grain sale model as done by Tronstad and Taylor (1989b). Thus, the incorporation of futures transactions into the grain-marketing decision greatly increases model complexity.

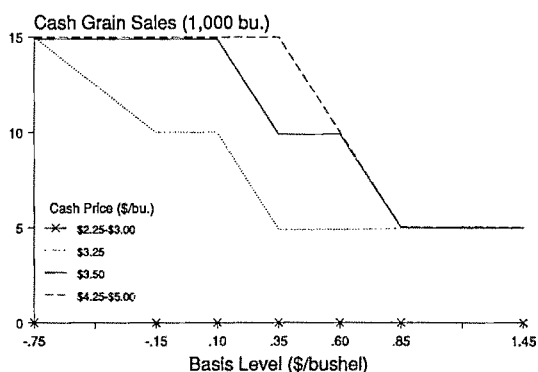

PANEL A. Storage Level = 5,000 bushels

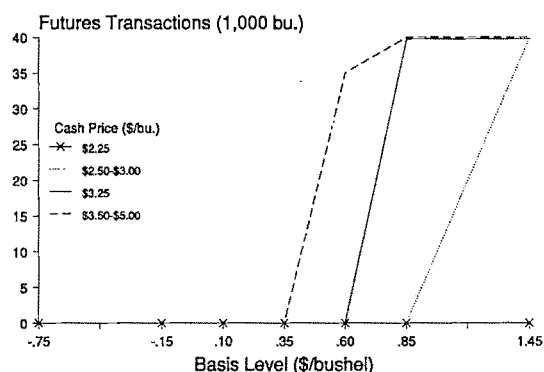

PANEL D. Storage Level = 5,000 bushels

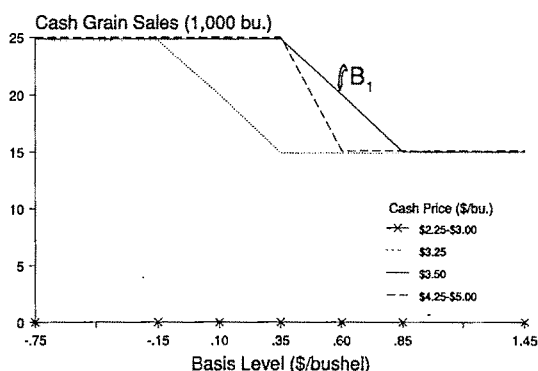

PANEL B. Storage Level = 15,000 bushels

PANEL E. Storage Level = 15,000 bushels

PANEL C. Storage Level = 25,000 bushels

PANEL F. Storage Level = 25,000 bushels

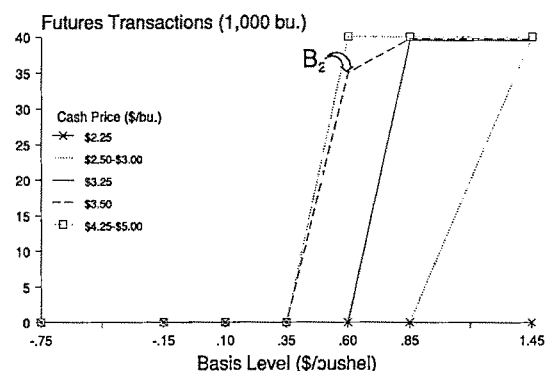

Figure 1. Optimal cash grain sales and futures transactions for April given a before-tax income level (I_t) = \$0.00, and quantity of March futures position (QM_t) = 0 bushels

basis (B_t), storage (ST_t), before-tax income (I_t), and short futures position (QM_t) for the firm are \$3.50 per bushel, \$.60 per bushel, 5,000 bushels, \$0.00, and 0 bushels, respectively, Panels A and D indicate that the firm should incur 0 bushels of cash grain sales (point A_1) and sell 30,000 bushels of March futures contracts (point

A_2). However, if the storage level for the firm were 25,000 bushels instead of 5,000 bushels, Panels C and F indicate that the firm should incur 20,000 bushels of cash grain sales (point B_1) and sell 35,000 bushels of March futures contracts (point B_2). Since optimal marketing decisions are linearly interpolated and occur in

5,000 bushels increments, cash price line "kinks" often appear in figure 1 at points where the basis level was discretized, as described earlier.

Results in figure 1 indicate that cash grain sales are generally preferred to hedging if the basis is less than \$.35 per bushel. However, because the basis level in conjunction with the cash price determine whether cash grain sales, futures transactions, and/or storage is most profitable, no cash grain sales or positive futures transactions occur for the lowest cash price state of \$2.25 per bushel, even when the basis level is at its lowest (-\$.75/bu.) or highest price state (\$1.45/bu.). For cash prices between \$2.50 and \$3.00 per bushel, storage is always preferred to cash grain sales and positive futures transactions do not occur until the basis level is above \$.85 per bushel. All of storage goes to cash grain sales for basis levels less than \$.35 per bushel and cash price levels above \$3.50 per bushel, whereas futures transactions occur at their upper limit whenever the basis and cash price levels are above \$.60 and \$3.50 per bushel, respectively.

Because harvest will occur before the upcoming March futures contract matures, the SDP model allows the producer to hedge anticipated production (AQ_t) in April (i.e., discrete amounts of AQ_t from 0 to 30,000 in 5,000 bushel increments). Therefore, the opportunity cost of selling grain in storage on the cash market is less for April through August since AQ_t can be substituted for storage (ST_t) to satisfy equations (9) and (10). Consequently, cash grain sales and futures transactions are greater for April than preceding months of the current tax year, given an initial storage level. Also, the time to maturity (TM_t) for March futures contracts is further away for April (i.e., eleven months) than any other month. Thus, *ceteris paribus*, higher basis levels are required to signal positive futures transactions for April than months which have a shorter time to maturity because TM_t had a significant and positive coefficient in explaining the basis level. In general, the basis level must be about \$.50 to \$.75 greater for lower cash price states (less than \$3.00) and about \$.25 to \$.50 greater for higher cash price states (greater than \$3.50) before hedging occurs at the same level for the month of April compared to months preceding March that are in the current tax year.

Figure 2 graphically depicts optimal cash grain sales and futures transactions for December. Because the month of December is crucial for income tax considerations, the state variables of before-tax income (I_t), basis (B_t), and cash price (P_t) vary in this figure. That is, the legend lines

of cash price in conjunction with the before-tax income state of the firm on the horizontal axes in figure 2 determine the optimal level of cash grain sales and futures transactions. For example, if the current levels of cash price, before-tax income, basis, storage, and short futures position for the firm are \$2.50 per bushel, -\$40,000, -.35 per bushel, 25,000 bushels, and 0 bushels, respectively, Panels B and E indicate that the firm should incur 20,000 bushels of cash grain sales (point A_1) and not take any short futures position (point A_2).

Results in figure 2 demonstrate several factors in relation to the potential income tax liabilities of the firm. First, as seen in Panels A, B, and C, cash grain sales generally decrease as the before-tax income level of the firm increases. This is because the marginal tax rate for the firm increases as the before-tax income level of the firm increases. Thus, grain storage is more generally profitable for a higher before-tax income state than a lower before-tax income state. However, as shown in Panel A of figure 2, cash grain sales increase for cash price states above \$3.25 per bushel and before-tax income levels above \$40,000. This is because the basis level (-\$.15/bu.) is not favorable for hedging transactions and the increase in the marginal tax rate is relatively small on additional grain sold if the before-tax income level is above \$40,000. Consequently, futures transactions can decrease as the before-tax income level of the firm increases at low basis levels.

Second, cash grain sales are greater for lower cash price states than higher price states at before-tax income levels less than -\$20,000. This is because cash grain sales for the high cash price states push the producer into a higher marginal tax bracket than the low cash price states. Also, cash grain sales are greater for December than preceding months at low cash price and before-tax income levels in order to take advantage of zero or near zero marginal tax rates. That is, for months preceding December, the cash price might increase before the next tax year begins, whereas December is the last month of opportunity for selling grain in the current tax year.

Although the effects of a March futures position (VM_t) or average transaction price (ATP_t) on optimal grain-marketing decisions are not graphically illustrated here, some general insights are noted. Results revealed that low ATP_t s usually have larger cash grain sales than high ATP_t s, because the revenue generated from closing a short futures position is greater for high ATP_t s than low ATP_t s. This additional revenue

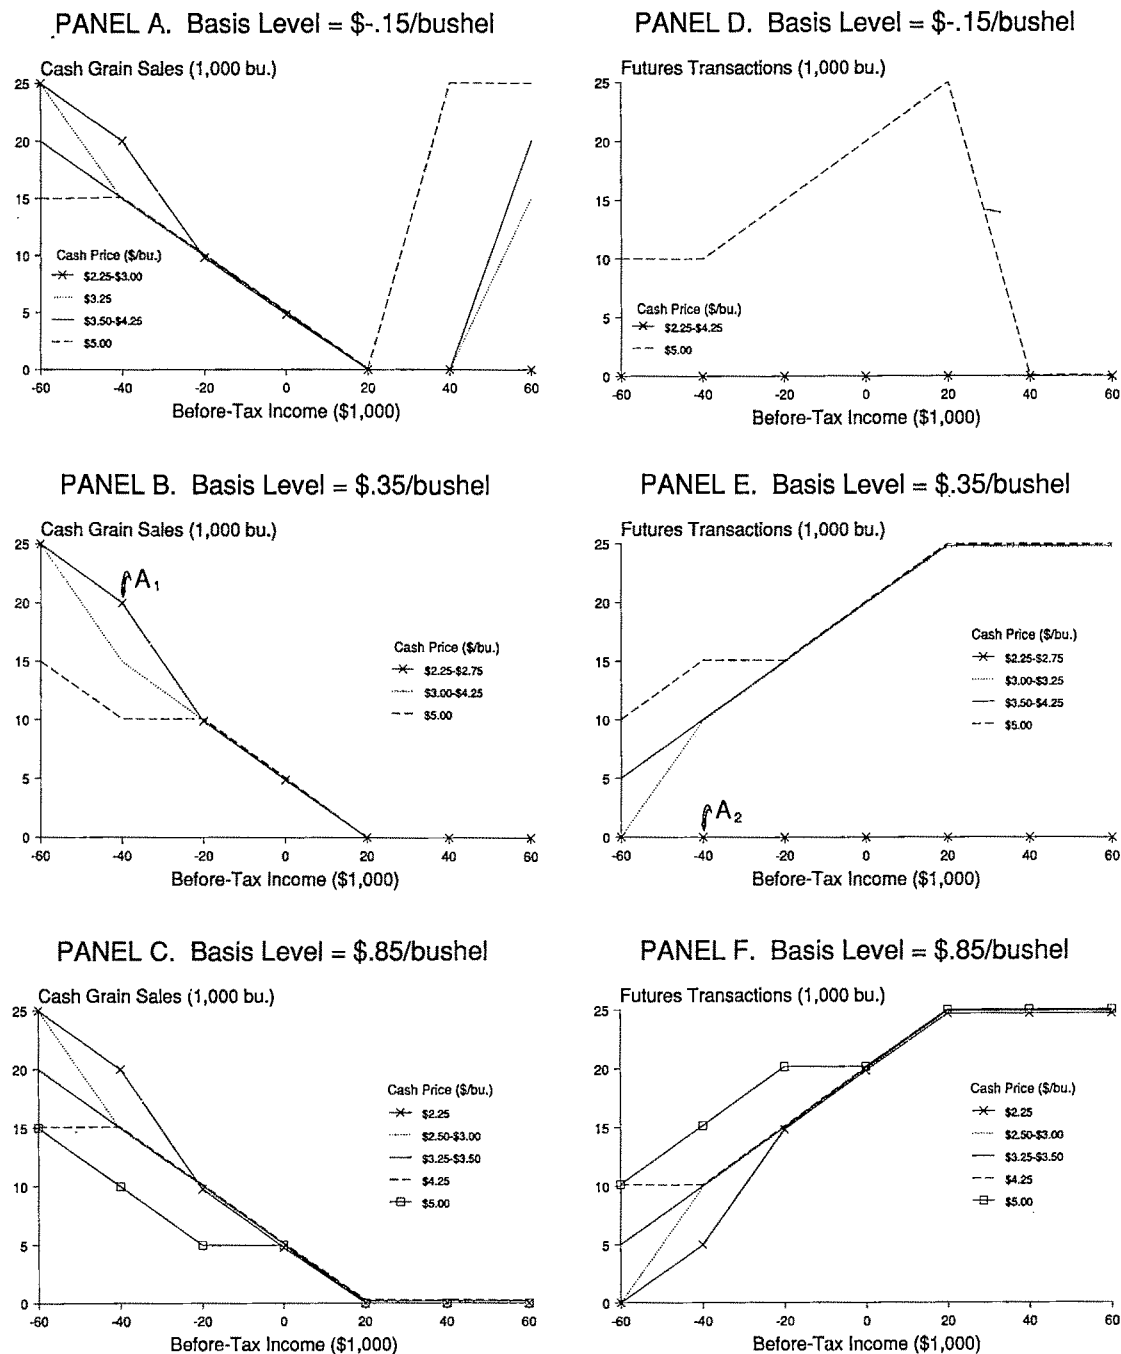

Figure 2. Optimal cash grain sales and futures transactions for December given a storage level (ST_t) = 25,000 bushels, and quantity of March futures position (QM_t) = 0 bushels

tends to increase the marginal tax rate of the firm and decrease the after-tax profitability of additional cash grain sales. Thus, lower optimal cash grain sales are generally given for higher ATP_t states.

The value associated with any short futures

position tends to be dominated by basis, cash price, and before-tax income level effects when determining optimal futures transactions. However, results suggest that lower ATP_t s are less profitable for closing out part or all of a short futures position for lower before-tax income

levels. This is because less revenue is generated from closing out a short futures position with a low *ATP*, than a high *ATP*, and income tax effects are not so dominating over the *ATP*, effect at lower before-tax income states.

In summary, results from the SDP grain model suggest that, not surprisingly, producers need to evaluate potential income tax liabilities as well as current market conditions when making grain-marketing decisions. To quantitatively evaluate the potential benefits from utilizing an SDP approach for grain-marketing decisions compared to other grain marketing strategies, the next section compares the post-sample performance of an SDP marketing strategy to other more traditional marketing strategies.

Comparison of Stochastic Dynamic Programming to Other Grain-Marketing Strategies

Profits are generated from August 1985 to January 1989, depending on the initial before-tax income level and grain-marketing strategy followed.⁵ Grain-marketing strategies considered were (a) 100% cash grain marketing with actual production divided equally for all months after harvest, (b) 100% utilization of futures contracts, (c) a minimum variance hedging ratio (MVHR) framework, and (d) the SDP model previously presented.

A MVHR represents the futures position that minimizes the variance associated with unequal price changes in the cash and futures markets during the hedge duration for a given case position (Witt, Schroeder, Hayenga). An MVHR framework is implementable since it does depend on individual preferences (Adler and Demple), and the MVHR is equivalent to an optimal hedging ratio under certain conditions (Heifner, Bond and Thompson). Utilization of a 100% cash or 100% futures marketing strategy would be equivalent to an MVHR strategy if the MVHR was 0 or 1, respectively. MVHRs were obtained by regressing annual cash price changes on futures price changes (e.g., see Witt, Schroeder, and Hayenga).

Futures transactions were closed during the contract maturity month of March. Thus, in calculating MVHRs for the post-sample evaluation, an additional observation was available

every March so that the MVHR was recalculated every year at this time. This procedure resulted in MVHRs of .6739, .6506, .8640, and .8778 for the time periods of March 1977 to March 1985, 1986, 1987, and 1988, respectively.⁶ For the SDP framework, cash price and basis transition probabilities were reestimated every year at harvest.⁷ Grain-marketing decisions from following either an all cash, all futures, MVHR, or SDP framework are illustrated in table 1.

Because the SDP model considers income tax liabilities, different grain-marketing decisions were generated depending on the initial before-tax income level of the firm in August 1985. Thus, different initial before-tax incomes are given in table 1 to illustrate income tax effects on grain-marketing decisions. Because most of the production costs occur after harvest, starting before-tax income states less than -\$20,000 were not considered.

For the 1985 tax year, starting with a before-tax income less than zero in August resulted in

⁶ In translating the continuous-static grain-marketing information of an MVHR into the discrete-dynamic nature of the hedging/production problem, the following steps were taken. First, actual production at the 1985 harvest was divided evenly between August 1985 and March 1986 (maturity time). Production allocated for each month was multiplied by the hedge ratio for the associated time period. A cumulative sum of the hedged amount for each month was started in August; and, when the cumulative sum exceeded 2,500 bushels, one March futures contract (5,000 bushels) was sold for that month. Similarly, when the cumulative sum exceeded 7,500 bushels, a second March futures contract was sold, and so on. After the quantity of grain to be hedged for this period was determined, remaining grain was evenly distributed by cash grain sales between August 1985 and March 1986. Then, all futures contracts that were previously sold were bought back in March and this grain was sold in the cash market. Results were essentially the same when using the month of February instead of March to close out futures contracts.

After March 1986, anticipated production was also utilized for making hedging decisions until harvest occurred. After harvest, the amount of grain hedged on anticipated production was subtracted from actual production. Then, this remaining grain was allocated between March futures contracts and cash grain sales as described above. The above grain-marketing procedure was utilized for all subsequent years in determining the grain-marketing activity generated by utilizing an MVHR framework or 100% utilization of futures.

The above procedure does not represent true MVHR. However, marketing decisions were also calculated from MVHRs that were updated monthly utilizing monthly differences of March futures prices. That is, in April the producer would make the initial hedge on anticipated production, and in August the producer's hedge would be based on actual production. Futures transactions were rounded to 5,000-bushel increments. Because the results of this procedure were inferior to the first procedure (i.e., on average, the cash position was \$9,924 less and the standard deviation of after-tax income was \$5,476 more as presented in table 3), these results are not reported here.

⁷ Equations estimated with data through August 1985, 1986, and 1987 are quite similar to those with data estimated through August 1988, i.e., equations (15) and (16). All equations are given in Tronstad and Taylor (1989a).

⁵ Expenses and revenues occur as described for the SDP model. Thus, the cash position is compounded monthly at a before-tax income rate of .5%.

Table 1. Harvest, Storage Level, and Short Futures Position of the Firm Illustrated Following Either an All-Cash, All-Futures, Minimum Variance Hedging Ratio (MVHR) or Stochastic Dynamic Programming (SDP) Strategy

^a Numbers in parentheses refer to the initial before-tax income level, e.g., (-20) refers to -\$20,000.

a strategy where all of the grain that was harvested should be sold in the current tax year. However, starting with a before-tax income of \$60,000 yielded a decision of selling only 5,000 bushels in the cash market for the current tax year. This demonstrates the importance of selling grain in storage to capitalize on low marginal tax rates and maintaining storage at relatively high marginal tax rates to reduce income tax liabilities. Winter wheat cash price levels were relatively low throughout 1986 so that cash grain sales did not occur in the SDP marketing strategy until December. Thus, even though the current cash price was relatively low, the after-tax profitability of selling some grain at a low marginal tax rate resulted in positive cash grain sales for December 1986. Cash prices continued to be relatively low throughout 1987, so the storage capacity of the firm (40,000 bu.) was reached in August 1987 with a harvest of 36,000 bushels. Thus, depending on the initial before-tax income for the SDP strategy, forced cash grain sales between 3,000 and 19,000 bushels occurred in August 1987. Cash price and basis levels moved upward through the latter part of 1987, and March futures contracts were sold in

October, November, and December utilizing the SDP framework.

As a result of widespread low soil moisture conditions in May of 1988, grain prices moved upward. This increase in prices indicated that March futures contracts and cash grain sales should occur under the SDP strategy. However, because of the severity of the drought, cash and futures price levels continued to rise throughout the summer of 1988. Because actual production at harvest was substantially less than that anticipated, the firm was forced to buy back some March futures contracts in August so that the short futures position of the firm would not exceed grain storage. Buying back March futures contracts at a much higher price in August and later on (including the termination point) resulted in a substantial before-tax income loss (anywhere from \$13,224 to \$23,948) for the SDP framework.

Also, the SDP decision rule with the highest initial before-tax income had the most grain in storage carried over every tax year because the benefit from storing grain into the following tax year is greater at high than low before-tax income states due to the progressive marginal tax

structure. Similarly, the short futures position of the firm was greater for the high than low initial before-tax incomes because cash grain sales are less lucrative for the high than low initial before-tax income levels.

Table 2 illustrates the cash position of the firm for the marketing strategies reported in table 1. Throughout most of the period, the cash position of the firm for the SDP framework is below (above) other grain-marketing strategies considered if the initial before-tax income was relatively high (low). This is because grain storage or less cash grain sales are desirable to reduce the income tax liabilities of the firm given a high initial before-tax income level. Conversely, cash grain sales are more desirable at lower initial before-tax income levels.

Table 3 analyzes the above marketing strategies by giving the mean and standard deviation of after-tax profits for the August 1985 through December 1988 period, the before-tax termination money received in January 1989 from closing out any outstanding futures position and selling all grain in storage on the cash market, the cash position of the firm at January 1989. The table also indicates the marginal tax rate that

would be required on all the excess before-tax termination income received in January from the SDP strategy over other strategies so that equal after-tax terminal wealth values would exist in January 1989. Thus, marginal tax rate figures for equality are calculated by dividing the differential in cash position on January 1989 with the differential of before-tax termination income received in January 1989, given that the SDP strategy received a higher before-tax termination value in January than the alternative strategy compared.

Results in table 3 show that the mean of after-tax income for the SDP strategy in the four tax years considered is sometimes less than that produced from the other marketing strategies. However, because of the additional revenue realized from selling all grain in storage and closing all futures positions at January 1989, the cash position of the firm at the termination point is anywhere from \$5,961 to \$25,021 higher for the SDP decision rule than all of the other marketing strategies considered. Also, 32% is the lowest marginal tax rate that would be required on all of the additional before-tax income received from the SDP strategy over all other strategies

Note: Accumulated after-tax profits of the firm through December 1988, the mean and standard deviation of after-tax profits realized, the before-tax termination money received in January 1989 from closing out any outstanding futures position and selling all grain in storage on the cash market, the cash position of the firm at January 1989, and the marginal tax rate that would be required on all the excess before-tax termination income received in January from the stochastic dynamic programming (SDP) strategy over other strategies so that equal after-tax terminal wealth values would exist in January 1989.

* NA signifies not applicable because the SDP strategy has a lower before-tax termination value in January than this case.

compared, and this tax rate is still relatively high. Furthermore, the standard deviation of after-tax income is less for the SDP approach than all other marketing strategies considered. This result is undoubtedly due in part from the SDP framework incorporating the progressive income tax structure into grain marketing decisions. It also demonstrates that the variability of after-tax income is not increased from utilizing an SDP framework of grain-marketing strategies, even though risk aversion is not explicitly incorporated into the model. Thus, the SDP strategy outperformed all of the other strategies in accumulating wealth and minimizing risk.

Concluding Comments

Results of this study suggest that cash grain sales are most advantageous for grain producers when

basis levels are low and the before-tax income level of the firm is relatively low. Because of discounting and the progressive marginal tax structure, income tax considerations are most pronounced toward the end of the tax year. Therefore, at low cash price and low before-tax income levels, cash grain sales are relatively higher at the end of the tax year than at the beginning of the tax year. If the before-tax income level of the firm is relatively high, the producer can still take advantage of favorable cash price levels without increasing the current income tax liabilities of the firm by hedging grain on a futures contract that will mature in the following tax year.

Increased storage levels are more conducive to larger cash grain sales and increased hedging activity. However, cash grain sales tend to increase the most at lower before-tax income levels, and futures transactions tend to increase the

most at higher before-tax income levels. Increasing the short futures position of the firm generally results in decreased cash grain sales and futures transactions because of the legitimate hedging constraint (i.e., short futures position of the firm cannot exceed the level of grain storage plus anticipated production before maturity or forty thousand bushels).

Changes in optimal grain-marketing decisions from the 1986 Tax Reform Act would undoubtedly be to store less grain because of lower marginal income tax rates, as concluded in Tronstad and Taylor (1989b). However, the reduction in storage from tax reform would be less for the model utilized in this analysis which also considers hedging. This reduction is especially true for basis levels above approximately \$.35 per bushel, or whenever a combination of hedging and storage is indicated to be a favorable tool for reducing income tax liabilities.

Depending on the initial before-tax income level and marketing strategy, a stochastic dynamic programming (SDP) framework accumulated from \$5,961 to \$26,021 more wealth than all other grain-marketing strategies considered for the August 1985 to January 1989 period. Also, profits generated from the SDP approach would have been much larger if the 1988 drought had been less severe; the drought caused March futures contracts sold in May and June to be bought back at a much higher price. Furthermore, all other marketing strategies yielded a standard deviation of after-tax income from 30% to 621% greater than that from the SDP framework. Thus, the SDP approach to grain-marketing decisions outperformed more traditional grain-marketing approaches which do not consider the dynamic and stochastic elements associated with income taxes.

Price Changes, Supply Elasticities, Industry Organization, and Dairy Output Distribution

Adesoji O. Adelaja

Long-run price elasticities of milk supply are decomposed into price elasticities of yield, herd size, and farm population. For northeastern U.S. dairy farms, these elasticities are shown to vary with farm size because of size-related differences in capital intensity, specialization, yield and herd size variability, and rates of entry/exit into dairy. In the short run, price responsiveness is shown to decrease with farm size. In the long run, large farms are shown to be most price responsive. Results suggest that lower milk prices could make revenue distribution less equal in both the short and long run by altering output and population distributions.

Key words: dairy revenue distribution, herd size, population, supply elasticity.

In the postwar years, the federal milk price support program played an important role in U.S. milk pricing and output regulation. The program stimulated much of the increases in real milk prices, total dairy output, and total dairy herd size from the mid-1960s to the early 1980s (Gardner). The program was also partly responsible for the declines in real milk prices, total milk output and total dairy herd size in the U.S. since the 1983 Dairy and Tobacco Adjustment Act (Klemme and Chavas). Since the passage of the 1983 act, agricultural economists and policy makers have more actively debated the impacts of price support policies and declining milk prices on the dairy industry (Gardner).

To examine the impacts of milk price changes, Chavas and Klemme, Klemme and Chavas, and Kinnucan and Forker recently revisited earlier studies by Halvorsen; Chen, Courtney, and Schmitz; Wipf and Houck; and Levins on milk supply response. The more recent, as well as the older, studies focused only on aggregate short-and/or long-run price elasticities of supply but ignored the possibility that supply response could

vary with farm size. The only disaggregate study of responsiveness to price changes in the dairy industry focused on input demand adjustments of dairy farms (Hoque, Adelaja, and Ganguly).¹

A correlation between price responsiveness and farm size might exist for several reasons. First, because capital intensity and specialization are likely to increase with farm size, the ability to vary cost and therefore output in the short run (in response to a price change) should decrease with firm size (O_i). Second, because the financial ability of a farm and thus its ability to vary fixed inputs (e.g., herd size) beyond the short run (in response to a price change) are likely to be directly correlated with its size, long-run supply responses of dairy farms may not be homogenous. Third, by encouraging firm entry (exit) into (from) dairy (Baumol, Panzar, and Willig 1982; Baumol), a price change can affect firm population. The rates at which such entry and exit occur and the rates at which incumbents change their sizes (crossover entry/exit) may vary with farm size grouping because sunk costs, which are barriers to entry/exit, may vary with farm size (Dunne, Roberts, and Samuelson). Because the long-run supply response encompasses the effects of prices on farm population

Review comments of associate editor John Braden and two anonymous *Journal* referees, the suggestions of Jim Seagraves, and Susan Howard's efficient word-processing assistance are greatly appreciated.

¹ Hoque, Adelaja, and Ganguly showed that input demand functions of dairy farms become more inelastic as farm size increases. Silberberg offered a theoretical explanation of the inverse relationship between input demand elasticities and firm size in competitive industries.

and farm size (Kislev and Peterson), it could also vary with herd size. Thus, aggregate short- and long-run supply elasticities may be misleading if they do not reveal farm-level supply responses.

By focusing on aggregate measures of short- and long-run milk supply elasticities, agricultural economists may have ignored several important effects of milk price changes. One effect involves the impacts of milk prices on the distribution of farm population by size. Knowledge of this is important in understanding the dynamics of dairy farm population, why farms enter and leave the dairy industry, and why some farm operators switch easily from farm to off-farm income. It could also be useful in planning government programs and services whose distribution is based on farm size. A second effect involves the differential impacts of milk prices on herd sizes and the relative differences among farms in potential herd expansion. Knowledge of these effects is useful in understanding the process of farm consolidation on dairy farms. Third are the differential impacts of milk prices on dairy output or revenue, which have equity implications for price related policies. Fourth are the differential impacts of milk prices on yield, which have implications for observed yield differences among farms. An understanding of all these aspects of price changes can enrich policy deliberations by enabling policy makers to consider both the aggregate and distributional effects of price changes and support policies.

The objective of this paper is to account for all the effects of dairy price changes discussed above. Specifically, the paper (a) conceptualizes the relationships between farm size and short-run/long-run output responsiveness, (b) presents a theoretical model for decomposing long-run supply elasticities into their components (the elasticities of yield, herd size, and dairy farm population), (c) presents a theoretical model for evaluating the output and revenue redistribution effects of price changes, (d) introduces the issue of equity into the price support debate, and (e) applies the models to panel data on a sample of northeastern U.S. dairy farms.

Supply Elasticity and Firm Size

This section conceptualizes the relationships between long-run elasticities of supply, short-run elasticities of supply, elasticities of yield, elasticities of herd size, and elasticities of population. It also conceptualizes how these elasticities

vary with farm size. The analysis draws on recent work on the effects of dairy price changes (Chavas and Klemme), on output flexibility theory (Mills and Schumann), and on contestability theory (Baumol).

If dairy farms cannot change the scales of their operations in the short run and if farm population cannot change in the short run, the only short-run outcome of a one-time price increase will be increased cow yield or output per cow (Chavas and Klemme).² This implies that the aggregate short-run price elasticity of supply (η) is equal to the aggregate short-run price elasticity of yield (γ). Chavas and Klemme showed that virtually all output adjustments (97%) made beyond the short run are accomplished through changes in total industry herd size (H). Thus, the short- and long-run price elasticities of yield are virtually equal, and output adjustments made beyond the short run are accomplished only through adjustments in the herd size of the average farm (\bar{H} or average herd size) and in the number of farms (N). This is because $H = (\bar{H})(N)$.

Baumol's theory of contestable markets and Kislev and Peterson's work on effects of price changes support the argument that output adjustments made beyond the short run involve increased farm population. That is, price increases (decreases) encourage entry and/or herd size expansion (exit and/or herd size contraction) if the market is competitive (Baumol, Kislev and Peterson). If one assumes that herd size proxies all fixed inputs, the difference between the measured value of η and the measured value of aggregate long-run supply elasticity (η^*) will be the aggregate price elasticities of average herd size (λ) and of farm population (β). That is, $\eta^* = \lambda + \beta + \gamma = \lambda + \beta + \eta$.³ The entire short-run adjustment in output will be captured in η , while the entire "beyond the short-run" output adjustment will be captured in $\lambda + \beta$.

Ladd and Martin cite the following reasons why $\eta^* \geq \eta$ or why $\lambda + \beta \geq 0$: (a) the fixity of some inputs in the short run, (b) imperfect knowledge or uncertainty, and (c) habit. First, because not all inputs are variable in the short

² Chavas and Klemme demonstrated this by showing that 100% of all short-run output adjustments of dairy farmers to a price change are accomplished through changes in yield.

³ Output (Q) = output per cow (\bar{Y}) times number of cows per farm (\bar{H}) times number of farms (N). Thus, $\partial \ln Q / \partial \ln P = \partial \ln \bar{Y} / \partial \ln P + \partial \ln \bar{H} / \partial \ln P + \partial \ln N / \partial \ln P$, where P is price and \ln is the natural log operator. Therefore, $\eta^* = \eta + \lambda + \beta$ and $\eta^* - \eta = \lambda + \beta$ if it is assumed that herd size and other fixed inputs are used in fixed proportion.

run (input fixity), the ability to vary output in the short run is more limited (limited to γ). Second, because producers may not be immediately aware of a price change (imperfect knowledge), output responsiveness is lower in the short run. Besides, producers may view short-run price changes as transient and therefore avoid costly investments or disinvestments such as herd size changes until it is confirmed that a price change is permanent. Third, producers may be so accustomed to current output and input levels (habit) that it takes some time to adjust output when price changes.

Assume that farms can be grouped by herd size and denote the disaggregate counterparts of the elasticities discussed above as η_i^* , η_i , γ_i , β_i and λ_i . The subscript i implies elasticities for farms in the i th size group. It will be shown below that each aggregate measure (η^* , η , λ , γ , or β) is the weighted average of its disaggregate counterpart (η_i^* , η_i , λ_i , γ_i , or β_i), whether or not the disaggregate one varies with farm size grouping. Note also that $\eta_i^* \geq \eta_i$ and that $\lambda_i + \beta_i \geq 0$, for each i (Chavas and Klemme, Ladd and Martin). The rest of this section conceptualizes how η_i^* , η_i , λ_i , γ_i , and β_i vary with herd size grouping.

Short-Run Supply Elasticity and Firm Size

In a competitive industry such as dairy, the short-run supply function for a firm is the portion of the marginal cost function that lies above the average variable cost function. The steeper the marginal cost function, the more inelastic the supply function and the more curved the average cost function (Stigler). Smaller firms will have flatter average cost functions and more elastic short-run supply functions, while larger firms have smaller η_i because they are less diversified and use more capital-intensive and specialized technologies (Mills and Schumann).^{4,5}

⁴ The reasons for this are as follows (Oi): Labor is relatively expensive, while capital is relatively inexpensive for large producers. The shadow value of managerial time is high for large firms because their managers have superior managerial ability and because their complex machinery-intensive technologies require specialized, highly paid, and highly skilled labor. Capital-intensive technologies have high adjustment costs, are less flexible, and are more efficient at high levels of output. Small firms choose labor-intensive technologies because wage rates they pay to the unskilled workers they employ are low.

⁵ Because some large dairy farms are diversified, an alternative hypothesis is that small farms are less output flexible. Output flexibility arising from diversification on large farms, however, is likely to be overshadowed by the inflexibility arising from low-capital intensity given that relatively few large farms are diversified (Tremblay).

These conditions hold for U.S. dairy, where large producers tend to utilize more capital-intensive technologies, more specialized technologies, and better skilled labor relative to smaller farmers. Besides, the evidence that increased capital/labor ratio, farm consolidation, and herd expansion have occurred simultaneously on dairy and other farms in the United States (Antle, Binswanger, Kislev and Peterson, Hoque and Adelaja) suggests that capital-intensive and inflexible technologies are synonymous with large-scale farming. Large dairy farms may be less capable of varying inputs, and thus output, in the short-run because more of their costs are fixed. The tendency of small dairy farms to rely more on off-farm income and to switch to off-farm employment when price falls (Adelaja and Rose; Salant, Smale, and Saupe) also suggests that small farms have larger η_i .

Long-Run Supply Elasticity and Firm Size

Both λ_i and β_i capture delayed (beyond the short run) reaction because of input fixity, uncertainty, imperfect knowledge, and habit (Ladd and Martin). Differences in λ_i and β_i among farms can be explained in part by differences in farmers' abilities to implement their reactions (degrees of fixity of assets, inputs, or technology). For example, the ability to vary herd size should be related to financial considerations. Larger and more capital-intensive farms, with greater borrowing capacity, should be more capable of varying herd size so that λ_i increases with herd size. If β_i is constant as size increases, the proportion of the total adjustments to a price change occurring in the short run would be greater for small farms than for large farms. Also, while η_i^* s would be more similar for small and large farms than η_i s, the adjustment period would be shorter for small farms.

To examine the relationship between herd size and β_i , suppose the market is perfectly competitive and thus perfectly contestable (Baumol). The industry will be vulnerable to hit-and-run entry because firms can enter when price increases and exit possibly even before price decreases.⁶ The probabilities as well as rates of entry (exit) into (from) farming at various levels

⁶ A purely competitive market is purely contestable (Baumol). Free entry and costless exit imply no cost discrimination against entrants or exitants beyond normal user costs and depreciation. Potential entrants are at no risk of any retaliatory price adjustment action by incumbent firms, and economic profit will be zero for all firms at long-run competitive equilibrium.

of size should be similar (β_i is constant but > 0) if there are no economies-of-scale advantages to large-scale production.⁷

In real life, sunk costs usually represent barriers to free entry and costless exit (Baumol and Willig; Baumol, Panzar, and Willig 1983; Weitzman). Sunk costs, which are a proportion of fixed costs (Baumol, Panzar, and Willig 1983), should increase with size. This relationship and the direct correlation between the degree of risk and firm size (Hall and Weiss, Mills and Schumann) suggest that β_i decreases with firm size if returns to scale are constant (CRS).

When long-run average cost is declining, the relationship between β_i and herd size is less clear. Increasing returns to scale, by itself, implies that β_i increases with firm size. For example, Kesides showed that entry increases with the degree of profitability of incumbents. Panzar and Willig's analysis also suggests this relationship. If profitability increases with firm size (Hall and Weiss) as a result of economies of scale, entry or exit encouraged by a given price change will increase with firm size if there are no sunk costs.

The evidence on economies of scale in dairy farming (particularly Northeastern dairy) suggests almost constant returns to scale (Hoque and Adelaja; Matulich; Hoque, Adelaja, and Ganguly) and an inverse relationship between the elasticity of population (β_i) and farm size. Small farms' greater reliance on off-farm income and their greater flexibility in switching from farm to off-farm income further suggests that these farms may be more capable of hit-and-run entry.⁸ In conclusion, the expectation for the dairy industry is that short-run supply elasticity (η_i) and population elasticity (β_i) decrease with farm size while the elasticity of average herd size (λ_i) increases with farm size, but that $\eta_i^* = \eta_i + \lambda_i + \beta_i$. The long-run impact of price changes on output is decomposed into the short-run impact (η_i), the elasticity of average herd size (λ_i), and the elasticity of population (β_i) in the next section to allow the examination of the impact of price changes on output distribution.

Price Changes and Output Distribution

Assume that dairy farms can be grouped into n groups based on herd size (e.g., 0–39, 40–79,

and 80 and above milk cows). Further, assume that milk cows and all other fixed inputs are used in fixed proportions so that herd size proxies all fixed inputs or enterprise scale. Denote total output of farms in the i th group as Q_i and total output of all farms as Q . Furthermore, assume that each of the i th groups has m_i farms such that the total number of farms in the industry (N) is $\sum_{i=1}^n m_i$ and the population share of farms in the i th group (b_i) is m_i/N . Thus, $Q_i = m_i \bar{Q}_i$ and $Q = \sum_{i=1}^n Q_i = \sum_{i=1}^n m_i \bar{Q}_i$, where \bar{Q}_i is the output of the average farm in the i th group.

Denote the yield of the average farm in the i th group as \bar{Y}_i , the total number of milk cows on farms in the i th group as H_i , and the herd size of the average farm in the i th group as \bar{H}_i , such that $H_i = m_i \bar{H}_i$. Total herd size in the industry (H) is $\sum_{i=1}^n H_i = \sum_{i=1}^n m_i \bar{H}_i$ and the i th group's share of $H(a_i)$ is $H_i/H = m_i \bar{H}_i/H$. Note that $\bar{Q}_i = \bar{H}_i \bar{Y}_i$, that $Q_i = m_i \bar{H}_i \bar{Y}_i$, and that average industry herd size (\bar{H}) is H/N . Total industry output is

$$(1) \quad Q = \sum_{i=1}^n Q_i = \sum_{i=1}^n m_i \bar{H}_i \bar{Y}_i.$$

The share of total output contributed by farms in the i th group (S_i) is

$$(2) \quad S_i = \frac{Q_i}{Q} = \frac{m_i \bar{H}_i \bar{Y}_i}{Q},$$

where $\sum_{i=1}^n S_i = 1$. Assuming further that all producers are price takers who receive the same price (P), the total aggregate supply elasticity (Π) is⁹

$$(3) \quad \Pi = \frac{\partial \ln Q}{\partial \ln P} = \sum_{i=1}^n \frac{m_i \bar{H}_i \bar{Y}_i}{Q} \cdot \left(\frac{\partial \ln \bar{Y}_i}{\partial \ln P} + \frac{\partial \ln m_i}{\partial \ln P} + \frac{\partial \ln \bar{H}_i}{\partial \ln P} \right) \\ = \sum_{i=1}^n S_i (\gamma_i + \lambda_i + \beta_i) \\ = \sum_{i=1}^n S_i \gamma_i + \sum_{i=1}^n S_i \lambda_i + \sum_{i=1}^n S_i \beta_i.$$

In (3), Π includes the farm population (entry and exit from outside the industry, and cross-over type of entry and exit), herd expansion (increase

⁷ Dunne, Roberts, and Samuelson provided empirical evidence that entry and exit rates are directly correlated and that both are higher for small producers *vis-à-vis* large ones.

⁸ Entry and exit could be so frictionless for small producers that they contribute to short-run output flexibility (Baumol).

⁹ Since $Q = \sum_{i=1}^n Q_i$, $dQ = \sum_{i=1}^n dQ_i$, $dQ/Q = d \ln Q = \sum_{i=1}^n (Q_i/Q) (dQ_i/Q_i) = \sum_{i=1}^n S_i d \ln Q_i$. Therefore, $\partial \ln Q / \partial \ln P = \sum_{i=1}^n S_i \partial \ln Q_i / \partial \ln P$. Since $Q_i = m_i \bar{H}_i \bar{Y}_i$, $\partial \ln Q_i / \partial \ln P = \partial \ln m_i / \partial \ln P + \partial \ln \bar{H}_i / \partial \ln P + \partial \ln \bar{Y}_i / \partial \ln P$. Therefore, $\partial \ln Q / \partial \ln P = \sum_{i=1}^n S_i [(\partial \ln m_i / \partial \ln P) + (\partial \ln \bar{H}_i / \partial \ln P) + (\partial \ln \bar{Y}_i / \partial \ln P)] = \sum_{i=1}^n S_i (\beta_i + \lambda_i + \gamma_i)$.

in herd size not sufficient to create crossover), and yield (increase in output at constant levels of herd size) effects of price changes.¹⁰

Because $N = \sum_{i=1}^n m_i$, the aggregate price elasticity of population (β), which measures the net change in total farm population from a price change, is

$$(4) \quad \beta = \frac{\partial \ln N}{\partial \ln P} = \sum_{i=1}^n \frac{m_i}{N} \frac{\partial \ln m_i}{\partial \ln P} \\ = \sum_{i=1}^n b_i \beta_i \neq \sum_{i=1}^n S_i \beta_i,$$

where $\sum_{i=1}^n b_i = 1$. Note that $b_i \neq S_i$. Also, because $H = \sum_{i=1}^n m_i \bar{H}_i$ and $\bar{H} = \sum_{i=1}^n (m_i \bar{H}_i / N)$, the aggregate price elasticity of average herd size (λ), which measures the net change in average industry herd size due to a price change, is

$$(5) \quad \lambda = \frac{\partial \ln \bar{H}}{\partial \ln P} = \sum_{i=1}^n \frac{\bar{H}_i}{\bar{H}} \frac{\partial \ln \bar{H}_i}{\partial \ln P} \\ = \sum_{i=1}^n \frac{H_i}{H} \frac{\partial \ln \bar{H}_i}{\partial \ln P} = \sum_{i=1}^n a_i \lambda_i \neq \sum_{i=1}^n S_i \lambda_i,$$

where $\sum_{i=1}^n a_i = 1$ and $a_i \neq S_i \neq b_i$. Also, define the industry's average yield (\bar{Y}) as $\sum_{i=1}^n S_i \bar{Y}_i$ and obtain the price elasticity of aggregate industry yield (γ), which measures the net increase or decrease in yield (via increased output at constant fixed inputs) as a result of a price change, as

$$(6) \quad \gamma = \frac{\partial \ln \bar{Y}}{\partial \ln P} = \sum_{i=1}^n S_i \frac{\partial \ln \bar{Y}_i}{\partial \ln P} = \sum_{i=1}^n S_i \gamma_i.$$

Now, consider what γ_i , λ_i , and β_i measure when estimated from grouped data on a sample of farms. The value of γ_i would measure the increase in yield as a result of a price increase for a representative farm in the i th group when herd size is held constant. Increases in yield when herd size is held constant does not imply crossover. On the other hand, λ_i measures the increase in the herd size for the same farm when crossover does not happen. Such an increase accrues beyond the short run (Chavas and Klemme). Because some farms are located close to their boundaries, a change in herd size can move them into the next herd size category and can affect the population of the next category (crossover entry and exit). β_i is a convolution of the effects of price changes on population via crossover en-

try and exit (by incumbents) and entry and exit in and out of the industry.

Because the group with the largest farms is unbounded from above (e.g., 80 cows to infinity), the value of β_i obtained econometrically from grouped data for this group may be high (even higher than β_i for other groups) because farms can only enter when price increases. This, however, would not necessarily imply an upward bias in the value of β_i . The high β_i value for this group would simply reflect the absence of an upper bound.

Considering that $S_i = m_i \bar{H}_i \bar{Y}_i / Q$, the price elasticity of output share (ϵ_i) is

$$(7) \quad \epsilon_i = \frac{\partial \ln S_i}{\partial \ln P} = \frac{\partial \ln m_i}{\partial \ln P} + \frac{\partial \ln \bar{H}_i}{\partial \ln P} \\ + \frac{\partial \ln \bar{Y}_i}{\partial \ln P} - \frac{\partial \ln Q}{\partial \ln P} = \beta_i + \lambda_i + \gamma_i - \Pi \\ = \beta_i + \lambda_i + \gamma_i - \sum_{i=1}^n S_i (\beta_i + \lambda_i + \gamma_i) \\ = \gamma_i - \gamma + \sum_{i=1}^n (1 - S_i) (\beta_i + \lambda_i).$$

Price Changes and Output Distribution in the Short Run

In the short run, one can assume that $\beta_i = 0$ and $\lambda_i = 0$ (Chavas and Klemme). In this case, equation (3) converges into $\Pi = \sum_{i=1}^n S_i \gamma_i$. Because $\gamma_i = \eta_i$ and $\gamma = \eta$ (Chavas and Klemme), the following is obvious:

$$(8) \quad \eta = \sum_{i=1}^n S_i \eta_i.$$

Equation (8) shows that the aggregate short-run supply response correctly predicts the farm-level short-run supply elasticity ($\eta = \eta_i \sum_{i=1}^n S_i = \eta_i$) only if all farms have similar η_i .

The short-run price elasticity of output share (Y_i) is obtained from equation (7) as

$$(9) \quad Y_i = \gamma_i - \gamma = \eta_i - \eta.$$

Equation (9) shows that if η_i is greater (less) than η , a price increase raises (lowers) the output share for the i th group. If, however, $\eta_i = \eta$, $Y_i = 0$ and price changes will not affect short-run output distribution. The necessary and sufficient condition for price changes to affect short-run output distribution is that η_i varies with farm size. Note that the magnitude of Y_i increases as the differences in η_i among farms increase. The

¹⁰ Crossover entry is defined as entry into a group as a result of exit from another group.

implications of equations (8) and (9) are the same for revenue distribution if the competitive pricing assumption is maintained.¹¹

Price Changes and Output Distribution in the Long Run

In the long run, β_i and λ_i are expected to be positive, λ_i is expected to increase with farm size and β_i is expected to decrease with farm size but only up to a point. The following long-run relationship between aggregate long-run supply elasticity and farm-level supply elasticity is obvious from equation (3):

$$(10) \quad \eta^* = \sum_{i=1}^n S_i \eta_i + \sum_{i=1}^n S_i \lambda_i + \sum_{i=1}^n S_i \beta_i \\ = \sum_{i=1}^n S_i (\eta_i + \lambda_i + \beta_i) = \sum_{i=1}^n S_i (\eta_i).$$

From equation (10), if there are differences in η_i^* , η^* will not correctly predict farm level supply response. The differences in η_i^* may come from differences in η_i , λ_i and γ_i . Even when the η_i s are similar, η^* will still not correctly predict farm level supply response as long as λ_i and β_i vary with farm size.

The long-run price elasticity of output share (Y_i^*) is obtained from equation (7) as follows:

$$(11) \quad Y_i^* = \gamma_i + \lambda_i + \beta_i \\ - \sum_{i=1}^n S_i (\gamma_i + \lambda_i + \beta_i) = \eta_i^* - \eta^* \\ = \eta_i - \eta + \sum_{i=1}^n (1 - S_i) (\lambda_i + \beta_i) \\ = Y_i + \sum_{i=1}^n (1 - S_i) (\lambda_i + \beta_i).$$

From (11), if the i th farm group's η_i^* is greater (less) than η^* , a price increase raises (lowers) the output share for the i th group in the long run. The requirement for price changes not to affect long-run output distribution is that all farms have similar η_i^* . Even if η_i s are similar ($Y_i = 0$), redistribution of output still occurs in the long

run if there are differences in λ_i and β_i . Note that if η_i^* are more similar than η_i , there may be an over redistribution of output in the short run which could be corrected for in the long run.

In evaluating the revenue redistribution effects of price policies, values of Y_i and Y_i^* derived from estimates of η_i , η_i^* , λ_i , and β_i can be used to project revenue and output shares that result from a given price change. They can also be used to construct Lorenz-type curves for output or revenue distribution (by plotting the cumulative percentage of farms against the cumulative percentage of output or revenue before and after an anticipated price increase or decrease). Finally, they can be used to calculate measures of output or revenue inequality such as the gini coefficient (G).

Panel data are ideal for estimating η_i , η_i^* , λ_i , and γ_i , and thus Y_i and Y_i^* for farms of different sizes. In this study, data on average farms in several size groups collected over time are used. Each time series on the average farm in a group is used to estimate the supply function for the group the farm represents. The short- and long-run price elasticities of the product of the output of the average farm in a group and the population of the group were used to approximate the weighted short- and long-run supply elasticities for the group.¹² This method is valid if the distribution of farms in the sample used approximates the distribution of the total population.

Evidence From Northeastern U.S. Dairy

The decomposition model above was applied to data available through the electronic farm accounting (ELFAC) system. This system is sponsored by the Cooperative Extension Service for the northeastern states. The system provides annual data on average farms in several groups for a sample of northeastern U.S. dairy farms. In annual ELFAC reports (Tremblay) available for the 1971 through 1985 period, average production and cost data are reported for small farms (less than 40 milk cows), medium-sized farms (40 to 79 milk cows) and large farms (80 or more milk cows). Specific variables upon which data are reported include herd size, dairy revenue, nondairy revenue, variable production ex-

¹¹ To evaluate fully the equity implication of price changes, the impact of price changes on profit distribution would be needed. This impact would require knowledge of the structures of the underlying cost functions for farms in various size groups and would introduce much greater methodological and analytical complexity. The discussion in this paper is limited to revenue distribution but the extension of this methodology to assess profit distribution is left to future research.

¹² Since $\bar{Q}_i = Q_i/m_i$, $m_i \bar{Q}_i = a_i \sum_{j=1}^m Q_{ij}$ where Q_{ij} is the output of the j th farm in the i th group. Therefore, $\partial \ln (m_i \bar{Q}_i) / \partial \ln P = \sum_{j=1}^m (Q_{ij}/m_i \bar{Q}_i) (\partial \ln Q_{ij} / \partial \ln P) = \sum_{j=1}^m r_{ij} (\partial \ln Q_{ij} / \partial \ln P)$ where $r_{ij} = Q_{ij}/m_i \bar{Q}_i$. This shows that the price elasticity of the product of population and the output of the average farm in the i th group is the weighted average supply elasticity for farms in the i th group.

penses, price received, milk sale in pounds, number of family workers, value of land, value of buildings, value of livestock, and value of equipment.

For each group, the mean of the annual values of herd size of the average farm (\bar{H}_i) and the coefficient of variation ($CV_{\bar{H}_i}$) were examined to determine variability of herd sizes. In the small herd size group, mean \bar{H}_i was 33 (maximum = 35, minimum = 32) and $CV_{\bar{H}_i}$ was 2.48%. In the medium herd size group, mean \bar{H}_i was 57 (maximum = 58, minimum = 55) and $CV_{\bar{H}_i}$ was 1.55%. In the large herd size group, mean \bar{H}_i was 122 (maximum = 130, minimum = 116) and $CV_{\bar{H}_i}$ was 3.72%. Mean \bar{H}_i for all farms was 71 (maximum = 75, minimum = 65) while $CV_{\bar{H}_i}$ was 4.43%. The size of the average farm seemed relatively stable over time. The higher $CV_{\bar{H}_i}$ value for large farms probably reflects the fact that herd size is unbounded from above. Because of the nature of the data, changes in \bar{H}_i indicate only herd expansion/contraction (λ_i) that do not involve crossover. Herd size changes involving crossover are captured in β_i .

The Koyck distributed lag specification was chosen over the Nerlove (partial adjustment) and Almon for estimating short- and long-run supply elasticities. Both the Koyck and the Nerlove are similar except in the structures of the stochastic disturbance terms and the interpretations of the adjustment paths of output. The Nerlove presumes that the search for new optimality after a price increase involves periods of overproduction and underproduction relative to the new optimal output level. Periods of overproduction seem unlikely given the reasons λ_i and β_i are expected to be positive. Both the Almon and the Koyck presume that continuous underadjustment ensues whereby output levels during adjustment approach the new optimal level as a limit. However, while the Koyck assumes that the proportion of adjustments made in a given time declines over time, the Almon assumes that the proportion increases and then decreases. The Koyck specification was used because of the expected short-run stickiness of population and herd size and the limited degrees of freedom imposed by the data.

The following Koyck supply function was specified for each group of farms:

$$(12) \quad \ln QM_{it} = \alpha_{i0} + \alpha_{i1} \ln PM_{it} + \alpha_{i2} \ln PF_{it} + \alpha_{i3} \ln PB_{it} + \alpha_{i4} \ln QM_{it-1} + U_{it},$$

where QM_{it} is the product of mean milk output (output of average farm) and number of dairy

farms in the i th group in time period t , PM_{it} is the real average price received by farmers in the i th group for milk in time period t , PF_{it} is the real weighted average price paid by farmers in the i th group for feed and concentrates in time period t , PB_{it} is the real average price received by farmers in the i th group for beef (a substitute product) in time period t , QM_{it-1} is the lagged value of the dependent variable (QM_{it}), and U_{it} is a stochastic error term. The coefficients of the models are α_{i0} , α_{i1} , α_{i2} , α_{i3} , and α_{i4} .

The model assumes that the effects of a one-time increase in PM , PF , and PB are distributed over time and that the weights decline geometrically. The estimate of short-run supply elasticity (η_i) is α_{i1} , the estimate of supply elasticity after the T th period is $\alpha_{i1}(1 - \alpha_{i4}^T)/(1 - \alpha_{i4})$, the estimate of long-run supply elasticity (η_i^*) is $\alpha_{i1}/(1 - \alpha_{i4})$, the mean lag is $\alpha_{i4}/(1 - \alpha_{i4})$, and the median lag is $\ln 0.5/\ln \alpha_{i4}$. The specification imposes the same lag structure on the impact of PM_t , PF_t , and PB_t on QM_t for farms in the same herd size group. Lag structures, however, are free to vary over the herd size groups.

The QM_{it} variable for a group was measured as the annual mean of output in hundredweights times the number of farms in the group because the distribution of the ELFAC sample is very similar to that of the northeastern population. PM_{it} was measured as the deflated values of mean prices received by ELFAC farmers. PF_{it} and PB_{it} were measured as the deflated values of the indexes of nominal prices paid by farmers for feed and received by farmers for beef in the Northeast (*Agricultural Prices*). The deflator used for all prices was the deflator for gross national product (DGNP) obtained from *The Economic Report of the President*.

To explain the relationships between λ_i , β_i , η_i , and η_i^* , a specialization index (SI_i) and a capital intensity index (CI_i) were calculated from the ELFAC data set. Annual values of SI_i for the average farms in each group were calculated as the percentages of total revenue derived from dairy-related activities. From the annual values of SI_i , mean values of \bar{SI}_i (\overline{SI}_i) were calculated. The estimated values of \bar{SI}_i for small, medium, large, and all farms were, respectively, 92.52, 94.20, 93.80, and 94.00. Because the values of \bar{SI}_i were significantly different at the 5% level for small and medium and for small and large farms (but not for medium and large farms), it was concluded that specialization increases very slightly with herd size but only up to a point.

Total variable cost (TVC_i) and total fixed cost (TFC_i) for the average farms were calculated to

obtain annual values of CI_i . TVC_i was calculated as the sum of expenses on all variable inputs including hired labor. The components of fixed costs were assumed to be fixed investments, family labor, and property taxes. Cost of family labor was calculated as the number of family workers times the agricultural wage rate per hour in the Northeast (*Farm Labor*) times forty hours a week times fifty-two weeks a year. Thus, the productivity of family and hired labor were assumed equal. Following Christensen and Jorgenson, the opportunity cost of fixed investments was calculated as the product of interest rate paid by farmers (*Agricultural Statistics*) and total asset value. TFC_i was calculated as the sum of the opportunity cost of fixed investment, family labor cost, and property taxes paid.

Total production cost (TC_i) was measured as $TVC_i + TFC_i$. Annual values of CI_i were obtained as the percentages of total cost that are fixed. The means of these annual capital intensity values ($\overline{CI_i}$) obtained for small, medium, large, and all farms were, respectively, 0.172, 0.202, 0.223, and 0.188. All were significantly different at the 5% level, supporting Mills and Schumann's argument that the degree of capital intensity increases slightly with herd size. Output share (S_i) measures calculated from the EL-FAC data set for 1985 were, respectively, .0726, .4251, and .5023 for small, medium, and large dairy farms. These are similar to the shares reported by the Agricultural Statistics Board (*Milk Production*) for the entire U.S. dairy industry.

Econometric Considerations

Ordinarily, serial correlation makes ordinary least squares (OLS) estimates unbiased but inefficient. With the Koyck specification and the introduction of a lagged dependent variable, OLS estimates are biased, inconsistent and inefficient (Pindyck and Rubinfeld) because the lagged dependent variable and the error term will be correlated and the correlation will not disappear as sample size increases (Griliches).¹³ Generalized differencing methods are not appropriate for the Koyck model (Wold). Generalized differencing would lead to biased estimates while techniques for eliminating the bias will lead to inefficient parameter-estimates (Pindyck and Rubinfeld).

The instrumental variable and maximum like-

lihood methods have been recommended for estimating Koyck models (Johnston). The former is chosen over the latter whose estimators are not exact maximum likelihood estimators but maximum likelihood conditional on the first few observations. The instrument used to replace the lagged dependent variable is the predicted value of the dependent variable based on a regression of the dependent variable on current and lagged values of the independent variables (excluding the lagged dependent variable). The instrumental variable models were estimated via generalized least squares.¹⁴

Results

Parameter estimates of the supply functions for small, medium, large, and all farms are reported in table 1. All α_{i1} coefficients are significant at the 5% level. All α_{i2} coefficients are significant at the 5% level with the exception of the α_{i2} for small farms which is significant only at the 10% level. All α_{i3} coefficients are insignificant at both the 10% and 5% levels, suggesting the irrelevance of beef prices in the determination of milk supply. All the α_{i4} coefficients are significant at the 5% level. The signs of all significant coefficients are consistent with expectations.

For each model, Glegser's test for heteroscedasticity was performed by regressing the absolute values of the residuals against the dependent variable. The hypothesis that heteroscedasticity was present was rejected in each case. Shapiro-Wilkes tests for nonnormality of the error terms also suggested normal distributions of the residuals.

The estimated values of η_i in table 2 support the hypothesis that short-run supply elasticity decreases with farm size. The values are also consistent with the capital intensity and specialization indexes, suggesting that small farms may have greater ability to vary feeding rates, concentrate ratios, and the levels of labor utilization, and to vary yield and output in the short run. As expected, median and mean lags are directly correlated with farm size. Also, as shown in table 2, the proportions of total adjustments in the output to a one-time price change completed in one year were 77% on small farms, 70% on medium sized farms, and 30% on large farms.

Estimated values of η_i for small, medium, and

¹³ The Durbin-Watson d -statistic is inappropriate when a regression contains a lagged dependent variable. The Durbin L -statistic is recommended for large samples.

¹⁴ The Proc Autocor default procedure in SAS was used.

^a Small farms = less than 40 milk cows; medium-sized farms = 40–79 milk cows; large farms = over 79 milk cows; and all farms = small, medium, and large farms combined. Double and single asterisk indicate significance at the 5% and 10% levels, respectively. Standard errors are parenthesized. Estimates generated by OLS. PM_t is real price of milk in period t ; PF_t and PB_t are real prices of feed and beef, respectively, in period t ; and QM_{t-1} is lagged value of QM_t . QM_t is the product of mean group output and group size in time t in hundredweights.

large sized farms are, respectively, 0.5204, 0.2665, and 0.2311. The aggregate short-run elasticity (η) of 0.3646, estimated from the data on all farms, exceeds η_i for medium and large farms but is less than η_i for small farms. The estimate of η is similar to Halvorsen's estimate of 0.30 for the United States, higher than Chavas and Klemme's estimate of 0.11 for the United States, higher than Chen, Courtney, and Schmitz's estimate of 0.16 for California, and lower than Levins' and Milligan's estimates of 0.91 and 0.63 for Mississippi. The results of this study are consistent with those of previous studies considering that dairy farms in California are

larger than those in the Northeast, which are in turn larger than those in Mississippi. However, it is somewhat contradictory that this study's estimates suggest more output flexibility than that of Chavas and Klemme, considering that dairies in the Northeast are generally smaller than in the rest of the United States.

Estimated values of η^* for small, medium, and large sized farms are, respectively, 0.6785, 0.3814, and 0.7585. The aggregate long-run elasticity of 0.5132 is lower than Levins', Milligan's, and Chavas and Klemme's estimates of 1.55, 1.57, and 6.69, respectively. The difference between the short-run and long-run supply

¹ Double and single asterisks imply significance at the 5% and 10% levels, respectively.

² Short-run and long-run price elasticities of yield assumed to be equal because the coefficients of the lagged dependent variables were insignificant at the 5% and 10% levels.

³ Long-run elasticity calculated as short-run elasticity divided by $(1 - \text{coefficient of the lagged dependent variable})$.

elasticities for medium-sized farms ($\lambda_i + \beta_i = 0.1140$) suggests that these farms do not make significant short-run yield adjustments, and do not make significant long-run herd size or population adjustments. The sources of short- and long-run inflexibility on mid-sized dairy farms may need further investigation. Small farms are very price responsive in the short run but do not make much additional adjustment in the long run ($\lambda_i + \beta_i = 0.1581$). Large farms, however, which are not very price responsive in the short run are even more price responsive than the small farms in the long run ($\lambda_i + \beta_i = 0.5274$). Large farms' flexibility comes from herd size expansion and population change. For all farms, $\lambda_i + \beta_i = 0.1486$, which suggests relatively little herd size and population adjustments overall.

The ideal procedure for decomposing $\eta_i^* - \eta_i$ into its components (λ_i and β_i) is to estimate equation (12) jointly with three other equations similar to it, but where $\ln QM_{it}$ is replaced with $\ln(\bar{Y}_i)$, $\ln(\bar{H}_i)$, and $\ln(\bar{m}_i)$ and to constrain the sums of similar elasticities in the other equations to the elasticity in equation (12). However, joint estimation of a system of seemingly unrelated equations with constraints and lagged dependent variables is complex. Instead, the yield, average herd size, and population models were estimated individually and without constraints using the instrumental variable method used to estimate equation (12). A summary of the results is presented in table 3.

All short-run price elasticities of yield (γ_i) were similar to the short-run price elasticities of supply (η_i). Also, the coefficients of the lagged de-

pendent variable in the yield equations were all insignificant. These results confirm the hypothesis that virtually all short-run output adjustments are accomplished through yield changes ($\gamma_i \approx \eta_i$). The observed inverse relationship between γ_i and herd size suggests that cow production efficiency (yield) measures obtained at any given point in time are dependent on prices. They also suggest more variability in the yield of smaller farms, relative to larger ones.

From the herd size equation, the coefficient for price was 0.0120 for small farms, 0.0141 for medium-sized farms and 0.0214 for large farms, while the long-run price elasticities of herd size were 0.0313, 0.0519, and 0.2131, respectively. These values suggest increasing λ_i as herd size increases, that virtually no herd size adjustment is accomplished in the short run, and that price increases stimulate little herd size expansion even in the long run on small and medium-sized farms. The high value of λ_i for large farms probably reflects the fact that this group is unbounded from above. For all farms, the short- and long-run elasticities of herd size were, respectively, 0.0193 and 0.1255.

From the population equation, the coefficients for price were 0.0561 for small farms, 0.0254 for medium-sized farms, and 0.0423 for large farms, while the long-run price elasticities of population were 0.1820, 0.0775, and 0.3352, respectively.¹⁵ These results suggest that the

¹⁵ Tests for heteroscedasticity and nonnormality were also performed on the yield, herd size, and population equations. Error terms in all equations were also found to be homoscedastic and normal.

Table 4. Percentage Changes in Revenues and Revenue Shares from a 50% Decrease in Milk Price

Measure of	Measured as	Small	Medium	Large	All
Initial revenue shares in 1985 (%)	S_i	7.26	42.51	50.23	100.00

Final output or revenue share (%)		6.94	47.00	46.06	

^a η and η^* are calculated as $\sum_{i=1}^n S_i \eta_i$ and $\sum_{i=1}^n S_i \eta_i^*$ and not as elasticities obtained from estimating supply function for all farms. This is because the estimated and calculated elasticities differ slightly.

^b SR and LR are notations for short run and long run, respectively.

population effect occurs primarily in the long-run and that β_i decreases with herd size, but only until the category with the largest farms is reached. As explained above, β_i for that group is expected to be high because the group's range is unbounded. This problem cannot be completely eliminated even when one breaks this extreme group into smaller groups (there will always be one group with an unbounded range). Fichtenbaum and Shahidi discussed the implications of this problem for estimated measures of income inequality.

Values of long-run supply elasticity implied by the three auxiliary models (yield, herd size, and population) were calculated as the sum of the short-run elasticity of yield, the long-run elasticity of herd size, and the long-run elasticity of population. The implied values of η_i^* were 0.7151, 0.3798, and 0.7820, respectively, for small, medium, and large farms, compared with the estimates of 0.6725, 0.3814, and 0.7585, respectively, obtained from equation (12). The differences are rather small.

In conclusion, it appears that λ_i increases as herd size increases, that negligible herd size adjustments to price changes are accomplished in the short run, and that price increases stimulate little herd size expansion even in the long run on small and medium-sized farms. These findings for small and medium-sized farms are consistent with Kisleev and Peterson's argument that price increases stimulate increased population but not increased herd size and that farm consolidation is caused by factors other than price.

The estimates obtained from the "all farm" data set are useful in evaluating the aggregate

effects of price changes on output via yield, population, and herd size. Because the data set does not involve any grouping, crossover entry and restrictions on herd size do not affect estimates of λ_i and β_i . Results from equation (12) suggest that 71% of all adjustments to a price change are accomplished in the short run ($\eta = 0.3646$), while 29% are accomplished beyond the short run ($\eta^* - \eta = 0.1486 = \lambda_i + \beta_i$). The estimates from the auxiliary models suggest that 63% of the adjustments beyond the short run are herd size adjustments, while 37% are population adjustments.¹⁶ This result contradicts Kisleev and Peterson's finding that price changes do not affect the average farm's size.

The estimates of Y_i and Y_i^* reported in table 4 were generated from the values of η_i and η_i^* obtained via equation (12). The Y_i measures for small, medium, and large-sized farms are, respectively, 0.2532, -0.0007, and -0.0361. The respective measures of Y_i^* are 0.0861, -0.2110, and 0.1661. For illustrative purposes, the effects of a 50% fall in milk prices are shown in table 5. The fall in milk price lowers the output and revenue shares of small farms by 12.66% but raises those of medium and large-sized farms by 0.35% and 1.805%, respectively, in the short run. Consequently, using the 1985 revenue share figures as baseline figures, the output or revenue share of small farmers is lowered from 7.3% to 6.3% in the short run, that of medium-sized

¹⁶ These percentages are obtained by dividing the long-run elasticity of herd size obtained from the yield equation by the sum of the long-run elasticities of herd size and population obtained from the yield and population equations.

farms is virtually unchanged, and that of large farmers is raised from 50.2% to 51.1%. In the short run, price decreases thus seem to help large farms capture a slightly larger share of the market, most of which comes from small farms.

In the long run, a 50% decrease in milk price reduces the revenue or output share of small farms from 7.3% to 6.9%. Thus, while the instantaneous response is a lower revenue share for small farms, the extent of the reduction is lower as time passes. Similarly, a 50% decrease in milk prices lowers the revenue share of large farms from 50.2% to 46.1% in the long run. Thus, while price increases help raise the revenue share of large farms in the short run, after all adjustments are completed, revenue share is actually reduced. The revenue or output share for medium-sized farms is increased from 42.5% to 47.0% in the long run.

The patterns of adjustments observed for the Northeast occur because small and large farms have more elastic long-run supplies than the overall industry supply while medium-sized farms have less elastic supply than the overall industry supply. The lack of flexibility on medium-sized farms helps them capture a larger share of the market in the long run when prices are falling.

The revenue and population data in table 5 are used to construct Lorenz-type curves in figure 1. In constructing figure 1, however, it is im-

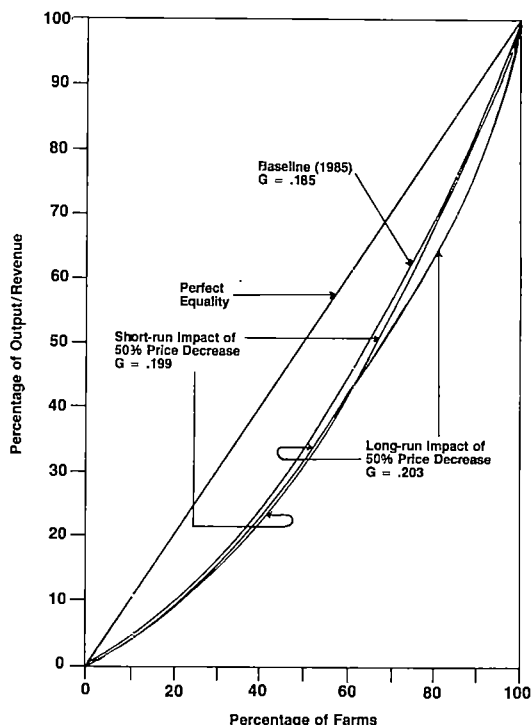

Figure 1. Lorenz curves depicting inequalities in dairy revenue distribution

Table 5. Distribution of Population, Output, and Revenue in Northeastern U.S. Dairy: 1985 and after a 50% Decline in Price

Measure	Herd Size			Gini Coefficient ^a
	Small	Medium	Large	
Population in 1985 and in short run

Cumulative percentage of revenue	6.3	48.9	100.0	0.199 ^b
Revenue in long run				
Percentage of revenue	6.9	47.0	46.1	
Cumulative percentage of revenue	6.9	53.9	100.0	0.203 ^c

^a Gini coefficient is calculated as $1.0 - \sum_{i=1}^n b_i(z_i + z_{i-1})$, where b_i is the proportion of farms in the herd size interval i and z_i is the proportion of total revenue received by farms in the herd size interval i and all lower intervals (Fichtenbaum and Shahidi).

^b Calculated with b_i evaluated at its 1985 level since $\beta_i = 0$ in the short run.

^c Calculated with b_i values resulting in the long run after population redistribution. The b_i values are based on β_i estimated of .182, .078, and .335, respectively, for small, medium, and large farms.

portant to note that a price change does not only cause output redistribution in the short and long run (through η_i , λ_i , and β_i) but also population redistribution in the long run. Therefore, one must project not only the new output distribution (which Y_i^* helps predict) but also the new population distribution if herd size intervals are held constant.

The elasticity of population share (Θ_i) is obtained through equation (4) as $\Theta_i = \partial \ln b_i / \partial \ln P = \beta_i - \sum_{i=1}^n b_i \beta_i = -0.0032$ for small farms, -0.1072 for medium-sized farms and 0.1498 for large farms. These values are based on the rough estimates of β_i of 0.182 , 0.078 , and 0.335 obtained from the estimation of the population function. Consistent with the assumption that all population redistribution occurs beyond the short run, there is no impact of price on population distribution in the short run (see estimates of population distribution in the short run in table 5). However, the long-run distribution of population will be such that population shares change to 16.4% , 53.8% , and 29.8% , respectively, for small, medium, and large farms, as indicated in table 5. These new population shares were plotted against the revenue shares to obtain the long-run Lorenz curve in figure 1.

The gini coefficient (G) for 1985 is 0.185 . For the situations in the short run and long run after a 50% decline in price, the G s are, respectively, 0.199 and 0.203 (table 5). The diagonal line in figure 1 represents perfect equality of revenue distribution ($G = 0$). Of course, all the Lorenz-type curves are below the perfect equality line ($G > 0$) because farm-level output increases with herd size. Consistent with the gini coefficients, figure 1 shows that a 50% price decrease marginally increases the area between the curve and the perfect equality line in the short run and further increases it in the long run. Reduced price support levels may therefore make revenue distribution more unequal in the short run and even more unequal in the long run. The extent of the revenue redistribution estimated for the northeastern dairy sector is minimal.

Conclusions and Implications

Economists have tended to ignore the effects of price changes on farm population and herd size and the possibility of heterogeneity in the short- and long-run output responsiveness of dairy farms. By conceptualizing and estimating disaggregate measures of supply response, this study

sheds some light on these aspects of price-related policies. The methodology employed in this study is potentially useful for researchers studying other subsectors of U.S. agriculture.

It is theoretically and empirically demonstrated that short- and long-run output responsiveness of dairy farms vary with farm size as a result of size-related differences in the elasticities of yield, herd size, and population. These differences can arise from differences in (a) degrees of capital intensity and specialization, (b) financial ability, and (c) magnitudes of barriers to entry, exit, and crossover. Moreover, differences in output responsiveness imply differentials in the impacts of price changes and price support programs on dairy revenues. The decomposition of the long-run supply elasticity into the elasticities of yield, herd size, and farm population, the conceptualization of the relationships between these elasticities and farm size, and the illustration of resulting revenue redistribution effects of price changes are novel features of this paper.

For the northeastern U.S. dairy sector, it is shown that recent declines in price support levels can create slightly greater inequality in revenue distribution. The limited potential for revenue redistribution in the Northeast does not necessarily suggest that revenue redistribution effects of price changes are always insignificant. Those effects may be significant in subsectors of U.S. agriculture characterized by large differences among farms in supply elasticity. The challenge to researchers is to identify the disparities in supply response before ruling out the possibility of revenue redistribution. In subsectors where significant variations in supply elasticity exist, proposals to change price support levels should consider both the primary beneficiaries and the output, revenue, and perhaps even the profit redistribution effects by employing disaggregate data and the type of analysis conducted in this study.

Does Arbitraging Matter? Spatial Trade Models and Discriminatory Trade Policies

Giovanni Anania and Alex F. McCalla

When modeling discriminatory trade policies, such as targeted embargoes or targeted subsidies, failure to explicitly include assumptions about the possibility of simultaneous exporting and importing may yield misleading results. Nonlinear programming and "vector sandwich" models implicitly set rules regarding arbitraging which may be at variance with actual policies and/or country behavior. The paper introduces an alternative spatial model which allows the researcher to explicitly incorporate her own assumptions about arbitraging. An analysis of the 1980 U.S. embargo to the USSR shows how the proposed model performs relative to the most frequently used spatial trade models.

Key words: arbitraging, discriminatory trade policies, embargo, spatial models, trade.

The explicit treatment of arbitraging behavior—that is, countries importing and exporting at the same time—in spatial trade models may be necessary for the models to produce valid results. The issue becomes important when analyzing discriminatory national trade policies intended to benefit friends and/or punish enemies. Examples of such policies include the Generalized System of Preferences (GSP), Lomé' Convention preferences, targeted export subsidies, PL 480, selective quotas, and targeted embargoes. These policies create multiple prices and generate possibilities to export and import simultaneously to take advantage of price spreads. Discriminatory trade policies include mechanisms to prevent arbitraging.

In this paper we argue that unless trade models explicitly incorporate the possibility of simultaneously exporting and importing, the choice of the trade model implicitly sets the assumptions on arbitraging. For example, spatial trade

models using reduced-form trade equations exclude the possibility of a country switching from one side of the market to the other as prices change, or of simultaneously exporting and importing.

In the first part of the paper we discuss the role of arbitraging in the design and management of discriminatory agricultural trade policies. The implications for trade policy analysis of different assumptions about arbitraging are briefly addressed. In the second part, the implicit hypotheses about arbitraging associated with two classes of spatial models, nonlinear programming (NLP) models (which include quadratic programming models as a special case) and vector sandwich (VS) models, are discussed.

An alternative model, presented in the third part of the paper, allows countries to switch from one side of the market to the other as prices change and permits the user to incorporate explicit assumptions about arbitraging. The model is an improvement over other spatial trade models when the policies to be analyzed include, for example, a trade liberalization when preferential trade agreements exist, an embargo, or a targeted export subsidy. A numerical example addresses arbitraging behavior associated with the 1980 U.S. embargo against the USSR and shows how the proposed model compares with frequently used models.

Discriminatory Agricultural Trade Policies and Arbitraging

World agricultural markets contain many discriminatory trade policies in which arbitraging behavior is a matter of concern. Examples include preferential tariffs, targeted export subsidies, embargoes, customs unions, food aid, and preferential import quotas. For example, countries using targeted export subsidies are concerned with preventing targeted importers from reexporting subsidized imports; countries granting preferential market access are concerned with preventing the reexporting of imports from non-preferred countries.

In the United States preferential agricultural tariff reduction agreements include the GSP, the Caribbean Basin Initiative, the Israeli free trade agreement and the recently concluded U.S.–Canada Free Trade Agreement. Other discriminatory trade policies include the Agricultural Trade Development and Assistance Act of 1954 (PL 480), the Export Enhancement Program (EEP), and a series of targeted embargoes including those against the USSR in 1974, 1975, and 1980–81. On preferential imports under its GSP scheme, the United States applies a “rule of origin” which requires that at least 35% (50% of two preferred countries involved) of the value of the article is added in the developing country. The same constraints apply to duty free treatment under the Caribbean Basin Initiative (Organization of American States). The United States–Canada free trade agreement contains a substantial set of “rules of origin” to prevent reexport when different third country tariffs apply in the two countries. PL 480 prevents concessional shipments from disrupting commercial markets (lowering prices) and seeks “commitment from participatory countries that will prevent resale or transshipment to other countries, or use (for other than domestic purposes) of surplus agricultural commodities purchased under the act” (sect. 101). In the early years of PL480, the United States did not apply the principle of additionality (sales must be in addition to commercial demand) to barter sales as it did to sales for local currency (Davis). Strong protests from other exporters about arbitraging of barter sales led to a modification of policy in 1957 (Mortensen, Ezekiel, Kristjanson).

Abbott, Paarlberg, and Sharples state that targeted export subsidies “are often criticized because arbitrage or rerouting of exports in transit can frustrate the subsidizing country’s policies. International trading firms or importing coun-

tries might benefit by reexporting subsidized commodities, as occurred early in the PL 480 program” (p. 724). To enter the EEC under the preferential tariffs granted by the Lomé Convention, exports from the African, Caribbean, and Pacific (ACP) countries must fulfill the conditions stated in Protocol 1 of the convention, concerning the definition of the concept of “originating products.”¹ A similar condition is contained in the EEC’s GSP scheme (EEC). Borrmann, Borrmann, and Stegger (pp. 117–20) argue that the “rules of origin” may have strongly affected the volume of trade generated through the EEC’s GSF scheme. A “country of origin” constraint is also contained in the ASEAN (Association of Southeast Asian Nations) agreement. Koester and Schmitz argue that Kenya imported sugar from the world market and exported it to the EC to capitalize on benefits due under the community preferential import policy. The popular Italian press claimed Israel is exporting frozen orange juice to the EC well in excess of its processing capacity (*La Repubblica*, Dec. 1986).

In all the preferential tariff reduction agreements, the constraints to assure that imports are originating in the beneficiary country are intended to avoid arbitraging and prevent third countries from exploiting the preferential policy. Constraints on the volume of exports receiving preferential treatment are usually included as well.

However, the various “rules of origin” still allow arbitraging. The preferred country can still find it feasible and profitable to import and export at the same time, using low price imports for domestic consumption while exporting domestic production at a higher preferential price. In this case, the quantity arbitrated is implicitly bounded by the “rules of origin” not to exceed domestic consumption.

Finally, a comprehensive study of economic sanctions by Hufbauer and Schott reports that the lack of cooperation of other countries often contributed to sanctions failure. In real-world discriminatory trade policies, arbitraging does matter. Failure to avoid arbitraging may jeopardize the accomplishment of the expected policy goals.

¹ Products originating in the ACP countries are defined, in simple terms, as products wholly obtained in one or more ACP countries, or products which have undergone sufficient working or processing within the ACP countries (third ACP-EEC Convention, signed in Lomé, Togo on 8 Dec. 1984).

Modeling Discriminatory Trade Policies

When discriminatory trade policies are considered, the determination of the net trade positions needs to be based on a spatial trade model, a model capable of reproducing trade flows between each pair of traders. Each region may buy (sell) from (to) different regions at different prices, collecting (paying) different per unit tariffs (subsidies). Any discriminatory trade policy can be equivalently expressed in terms of a tariff or a subsidy. Targeted embargoes are equivalent to country-specific prohibitive export tariffs. Country-specific export (import) quotas may be translated into two export (import) taxes: one, equal to zero, active up to the quota ceiling; the other, prohibitive, active above that ceiling. Food donations represent volume constrained subsidized exports.

Any spatial trade model solution is such that, for each pair of countries, say country i and country j , the domestic prices (p_i and p_j , respectively), must satisfy the following relations (as long as no binding constraint is imposed on the trade flow between the two countries):

$$(1) \quad (p_j - p_i - t_{ij} + \sigma_{ij} - \pi_{ij}) \leq 0;$$

$$(2) \quad (p_j - p_i - t_{ij} + \sigma_{ij} - \pi_{ij})x_{ij} = 0;$$

where t_{ij} is the fixed transportation cost to ship one unit of the commodity from region i to region j , σ_{ij} is the export subsidy that country i pays to its producers for each unit exported to country j , π_{ij} is the import tariff that country j imposes on each unit it imports from country i , and x_{ij} is the nonnegative trade flow from country i to country j . If the trade flow from country i to country j is positive, then the per unit transportation cost plus the tariff minus the subsidy must give the wedge between the two domestic prices. If no shipments occur from country i to country j , then the difference between the two domestic prices must be smaller or, at most, equal to the transportation cost plus the tariff minus the subsidy (implying that shipments from country i to country j are not profitable).

Without interventions, the only possible wedges between domestic prices of trading countries are transportation costs. The matrix of the transportation costs is consistent, which means that the minimum cost path to ship from region i to region j is always the one directly connecting the two regions. In this case, there is no rationale for arbitraging. Finding the market equilibrium solution does not depend on differentiating between transportation costs, subsi-

dies, and tariffs. Given domestic demands and supplies, all that matters is the net sum of the transportation cost plus the import tariff minus the export subsidy for each ordered pair [i.e., pairs (i, j) and (j, i) are different] of countries. This quantity represents a generalized transfer cost. The addition to and subtraction from the transportation costs matrix of nondiscriminatory tariffs and subsidies does not affect its consistency. However, this property may be disrupted by discriminatory trade policies.²

Most agricultural trade models are based on an a priori definition of the sets of the importing and exporting regions. Each country is represented through its excess demand or supply schedule. Thus, the possibility of arbitraging and of a country switching from one side of the market to the other as prices change is assumed away.

When each country's position on the world market is not set a priori, the assumptions about arbitraging are (implicitly) left to the structural characteristics of the specific model.³ These assumptions may strongly affect the solution obtained. For example, in a model with no transportation costs, and each country left free to export and import at the same time, the imposition of a tariff by an importing country on its imports from all but one of the other countries leaves each country's net trade position unchanged. Only trade flows change because the demand of the tariff-imposing country will be satisfied by the exporting countries bypassing the tariff by costlessly rerouting their exports through the preferred country. However, a very different outcome is obtained if regions cannot import and export at the same time.

Discriminatory Trade Policies and Commonly Used Trade Models

Nonlinear Programming Models

The most commonly used spatial trade models are the Quadratic Programming (QP) models developed by Takayama and Judge (Thompson, p. 28) in which an artificial quadratic net quasi-welfare function is maximized subject to a set

² It can vanish as a result of the implementation of preferential tariffs or targeted subsidies. It is lost when country-specific embargoes are imposed. The generalized transfer costs matrix being no longer consistent is a necessary, but not sufficient, condition for arbitraging to be profitable.

³ It should be noted, as pointed out by a reviewer, that spatial trade models, because of their homogenous good assumption, tend to overemphasize the occurrence of arbitraging. Hence, it is wise to use caution when considering commodities for which this assumption appears to be particularly strong.

of linear constraints. The quasi-welfare function is given by the sum of consumers' and producers' surpluses over all the regions considered. Linear demand and supply functions, large countries, and perfect competition in domestic and world markets are assumed (Takayama and Judge 1964 and 1971, Bawden, Takayama). Rowse expanded the QP formulation of the model to include nonlinear demand and supply functions. Thus, the classical QP model is a special case of the more general nonlinear programming (NLP) formulation.

Takayama and Judge (1971, chap. 10) propose a framework to analyze trading when tariffs and subsidies are present and suggest that it can also be used when discriminatory trade policies are active.⁴ They propose two alternative modeling approaches, based on domestic demand and supply functions (Takayama and Judge 1971, chap. 7, 8), and on excess supply/demand functions (Takayama and Judge 1971, chap. 9). They claim that in a large spectrum of cases the two models are equivalent, and that the second one may be more efficient. However, when discriminatory trade policies are considered, the equivalence of the two models may vanish.

The first model, which uses domestic demand and supply functions, leaves each country free to import and export at the same time but implicitly constrains imports to not exceed domestic consumption. The second model leaves the possibility of arbitrage totally free. These results can be easily verified by comparing the Kuhn-Tucker conditions associated with the two models.⁵ When the first model is used and the

constraint on arbitrage is binding, the arbitrage country's consumption and production prices are not equal. The consumption price is linked to the low price in the region(s) where the imports come from, while the production price is linked to the high price in the region(s) exports are shipped to. This implicit constraint on arbitrage reproduces a condition similar to that imposed by the "rules of origin" observed in real-world preferential trade agreements.

When discriminatory trade policies are present, the two models can yield different results. This will be the case when the solution obtained by using the model based on excess demand and supply functions is such that (a) at least one region exports and imports at the same time, and (b) its imports exceed its consumption.

When each country is represented as both a consuming and a producing region, the Kuhn-Tucker conditions of the NLP problem as formulated by Rowse are analogous to those of the QP formulation of the model based on domestic demand and supply functions. Arbitrage is possible, but in each country imports cannot exceed domestic consumption. If each region is a priori defined as an importer or as an exporter, then, a no-arbitrage constraint is implicitly imposed. The assumptions about arbitrage implicit in nonlinear programming models are summarized in table 1.

Whenever the classical QP models or NLP models are used to analyze markets characterized by discriminatory trade policies such that the generalized transfer costs matrix is not consistent, assumptions about arbitrage are implicitly made. Such assumptions may have serious implications for the trade policy analysis.

Vector Sandwich Models

MacKinnon (1975, 1976) proposed a vector sandwich procedure to solve spatial trade equilibrium problems.⁶ The procedure allows for nonlinear demand and supply functions as well as transportation costs. Holland developed a microcomputer program based on MacKinnon's procedure to solve relatively small, single commodity, spatial equilibrium models. Holland's program is capable of handling import and export tariffs, both ad valorem and per unit. Constraints may be imposed on specific flows as well as on individual countries' overall imports or

⁴ "In this example we use the same demand and supply functions and transportation costs as in chapters 7 and 8, but assume that $\pi_{21} = 1$ and $\pi_{31} = 1$. It is not necessary to assume that $\pi_{1j} = \pi_{2j} = \dots = \pi_{nj}$ for all j ; that is, the tariff may be discriminatory" (Takayama and Judge 1971, p. 201).

⁵ For the quantity formulation of the model based on the domestic demand and supply functions the Kuhn-Tucker conditions are given in (7.2.9.d) in Takayama and Judge 1971, p. 133; the analogous conditions for the price formulation of the same model are given in (8.3.7.a) and (8.3.7.b), p. 159 (the equivalence of the price and the quantity formulations is proven in Takayama and Woodland). These conditions imply that, if the domestic price is different from zero, (a) domestic consumption must be equal to the portion of the domestic production which is consumed domestically plus the sum of all the imports from the other countries, and (b) domestic production must be equal to the portion which is consumed domestically plus the sum of all exports to the other regions. Each country may import and export at the same time, with the constraint that in each country imports cannot exceed domestic consumption. When domestic consumption is entirely satisfied through imports, domestic production is entirely exported. For the second model, the one based on the use of excess supply/demand functions, the Kuhn-Tucker conditions are given in (9.1.27.d), p. 182, and in (9.3.4), p. 194. In this case, if the domestic price is different from zero, domestic production minus domestic consumption plus imports minus exports must be equal to zero. Arbitrage is now left totally unconstrained.

⁶ A good introduction to fixed point theory as a tool in finding economic equilibrium solutions is Zangwill and Garcia, chapters 5, 6, and 7.

Table 1. Implicit Assumptions About Arbitraging of the QP, NLP, and VS Models

Model	Each Country is Represented through:	Implicit Assumptions About Arbitraging
Quadratic programming models (Takayama and Judge 1964 and 1971, Bawden, Takayama)	linear domestic demand and supply functions	arbitraging allowed but constrained not to exceed domestic consumption (imports cannot be reexported)
	a continuous linear excess demand and supply function	arbitraging allowed and unconstrained
Nonlinear programming models (Rowse)	nonlinear domestic demand and supply functions	arbitraging allowed but constrained not to exceed domestic consumption (imports cannot be reexported)
	a nonlinear excess demand or supply function	arbitraging not allowed
Vector sandwich models (MacKinnon 1975 and 1976, Holland)	linear or nonlinear domestic demand and supply functions	arbitraging allowed but constrained not to exceed domestic consumption (imports cannot be reexported)
	a linear or nonlinear excess demand or supply function	arbitraging not allowed

exports. However, discriminatory tariffs and subsidies are not explicitly considered, although the user can overcome the problem by providing the generalized transfer costs instead of the transportation costs. Applications of the vector sandwich method in agricultural trade policy analyses include Holland and Sharples, USDA (chap. 11), Haley, and Kahn and Meilke.

If each country is considered as both consuming and producing, arbitraging is allowed but, again, it is constrained not to exceed domestic consumption. Each country may import and export at the same time, but imports may not be reexported (table 1).

The Model

In this section a spatial trade model is presented to analyze settings where discriminatory trade policies make the generalized transfer costs matrix inconsistent. The model has two main features: (a) each country can move from one side of the market to the other as prices change, and (b) the user is allowed to explicitly specify assumptions on arbitraging through two sets of parameters. The model is given in two forms, one based on domestic supply and demand functions, the other based on excess demand/supply functions. These functions need not be linear. The model based on domestic demand and supply functions can be constrained so that arbitraging (a) cannot occur, (b) is allowed but is constrained not to exceed domestic consump-

tion, or (c) is allowed and left completely unconstrained. When using the model in which each country is represented through its excess demand/supply function, only the first and the third scenarios can be implemented (table 2). The main advantage of the model we propose over the commonly used models is that it provides the researcher with the possibility of easily comparing within a single model structure the effects of discriminatory trade policies under different hypotheses about arbitraging.

Only one commodity is considered in the model proposed. In addition, a partial equilibrium framework, fixed exchange rates, and perfect competition on domestic and world markets

Table 2. Assumptions About Arbitraging Which Can Be Explicitly Incorporated in the Model Proposed

Each Country is Represented through:	Assumptions About Arbitraging Which Can Be Explicitly Incorporated
Linear or nonlinear domestic demand and supply functions	Arbitraging allowed and unconstrained
	Arbitraging allowed but constrained not to exceed domestic consumption
	Arbitraging not allowed
A linear or nonlinear continuous excess demand and supply function	Arbitraging allowed and unconstrained
	Arbitraging not allowed

are assumed. The model maximizes an artificial quasi-welfare function (W) defined as in Samuelson, Takayama and Judge, and Rowse. When domestic demand and supply functions are considered, the model may be stated as follows:

$$(3) \quad \max_{x_{ij}} W = \sum_i \theta_i(y_i) - \sum_i \phi_i(s_i) - \sum_{ij} [(t_{ij} + \pi_{ij} - \sigma_{ij})x_{ij}],$$

subject to

$$(4) \quad \xi_i^2 \left\{ [1 - (\xi_i - 1)/-2] \left[\sum_j x_{ji} - x_{ii} \right] + [(\xi_i - 1)/-2] \left[\sum_j x_{ij} - x_{ii} \right] \right\} = 0, \\ i = 1, \dots, n;$$

$$(5) \quad \Psi_i \left(\sum_j x_{ji} - x_{ii} \right) - y_i \leq 0, \quad i = 1, \dots, n;$$

$$(6) \quad x_i = \sum_j x_{ij} - \sum_j x_{ji}, \quad i = 1, \dots, n;$$

$$(7) \quad y_i = \max\{x_{ii}, x_{ii} - x_{ij}\}, \quad i = 1, \dots, n;$$

$$(8) \quad s_i = y_i + x_i, \quad i = 1, \dots, n;$$

$$(9) \quad x_{ij} \geq 0; \quad i, j = 1, \dots, n;$$

where i and j denote the regions ($i, j = 1, 2, \dots, n$); y_i denotes the quantity consumed in country i ; s_i denotes the quantity produced in country i ; $\theta_i(y_i)$ denotes the integral under the inverse domestic demand of region i , $p_i^d(y_i)$, between 0 and y_i ; $\phi_i(s_i)$ denotes the integral under the inverse domestic supply of region i , $p_i^s(s_i)$, between 0 and s_i ; x_{ij} denotes the flow of commodity from region i to region j ; x_i denotes the total exports (if positive) or the total imports with the sign changed (if negative) of region i ; t_{ij} denotes the fixed per unit transportation cost for shipping the commodity from region i to region j ; π_{ij} denotes the per unit tariff imposed by region j on its imports from region i ; σ_{ij} denotes the subsidy paid by region i for each unit exported to region j ; ξ_i denotes a parameter controlling the possibility of the i th region to arbitrage, and, if arbitraging is not allowed, the side of the market on which it appears (this parameter may be set to be equal to -1 , 0 or 1 : it will be equal to 0 for the nonbeneficiary re-

gions, and for the beneficiary ones which are left free to arbitrage; to -1 for the beneficiary countries which are not allowed to arbitrage and may operate on the market as importers only, to 1 for those which are not allowed to arbitrage and may operate on the market as exporters only and Ψ_i denotes a parameter constraining arbitraging, when it is allowed, not to exceed domestic consumption (it will be equal to 1 when country i 's imports must not exceed its domestic consumption, to 0 otherwise).

Constraints (6)–(9) are self-explanatory. When Ψ_i in (5) is set equal to 1 , arbitraging cannot exceed domestic consumption. When Ψ_i is equal to 0 arbitraging is not constrained by (5). Constraint (4) allows the user to impose that region i do not arbitrage. When arbitraging is not allowed, (4) provides the model with the position to be taken in the market (importer/exporter) by each region.⁸

Once the model is solved, equilibrium prices are computed as

$$(10) \quad p_i^d = p_i^d(y_i^*); \quad i = 1, \dots, n;$$

$$(11) \quad p_i^s = p_i^s(s_i^*); \quad i = 1, \dots, n.$$

Each country's producers and consumers welfare is defined (fig. 1) as the area between the inverse demand function and the price (the consumers' price if consumers and producers prices are not equal) line, plus the area between the price (the producers' price if consumers and producers prices are not equal) line and the horizontal axis or the inverse supply function, plus the tariff revenue (which is assumed to be redistributed to consumers and producers as a lump sum transfer):

$$(12) \quad W_i = [\theta_i(y_i^*) - y_i^* p_i^d(y_i^*)] + \left[p_i^s(s_i^*) s_i^* - \int_{\max\{0, s_i^*\}}^{s_i^*} p_i^s(s_i) ds_i \right] + \sum_j \pi_{ji} x_{ji}, \quad i = 1, \dots, n$$

⁷ Nonlinear transportation costs may be easily included. They are assumed to be linear to keep the discussion as close as possible to the standard QP setting.

⁸ In the case of a preferential tariff, for example, each beneficiary country has to impose a prohibitive tariff either on its imports or on its exports. The decision on which kind of tariff to implement implies an explicit policy choice: Imports are taxed when the country wants to make use of the preference. Exports are taxed, to make arbitraging unprofitable, when it finds itself better off by importing. The decision is based on the maximization of the beneficiary country's welfare. In many cases, this choice may be easy, as it is the case when only one country is granted a preferential treatment and it is already exporting prior to the implementation of the preferential tariff. In other cases the choice may not be so obvious (Asia). An importing beneficiary country may reach, for example, a higher welfare by remaining on the importers' side of the market even if the preferential treatment granted would make it possible for it to switch to being an exporter.

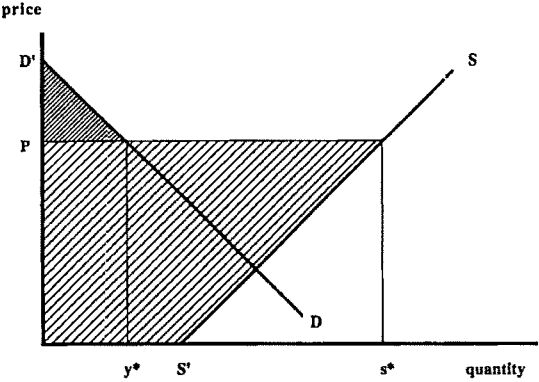

Figure 1. Welfare components for an exporting country

where S'_i is the intercept of the inverse supply function on the horizontal axis. In figure 1 $S'S$ is the inverse supply function, $D'D$ is the inverse demand function, p is the equilibrium price, y^* and s^* are the quantities consumed and produced, respectively, and the crosshatched areas sum to the country's producers' and consumers' welfare.

Often estimates of the domestic supply and demand functions for each region are not available, while estimates of the excess demand/supply functions are. In addition, the excess functions can be more easily estimated. Thus, a model formulation based on excess functions is presented as well. The structure of this model is essentially the same as the one based on the domestic demand and supply schedules. In figure 2 a simple two-country world market case

is presented. S_aS_a and S_bS_b are the inverse excess demand/supply functions of countries A and B, respectively. The market equilibrium is such that region A imports $-X_a$ from region B ($-X_a$ is equal to X_b). The equilibrium prices in the two regions are P_a and P_b , respectively. The difference between the two prices is equal to the transportation cost of shipping one unit from B to A, plus the per unit import tariff imposed by country A, minus the per unit export subsidy paid by country B. The crosshatched areas in figure 2 represent the gains from trade. When excess supply/demand functions are used, W , the artificial quasi-welfare function, may be defined as

(13)

$$W = \sum_i [-\chi_i(x_i)] - \sum_{ij} [(t_{ij} + \pi_{ij} - \sigma_{ij})x_{ij}],$$

where $\chi_i(x_i)$ denotes the integral under the inverse excess supply/demand function of region i , $p_i(x_i)$, between 0 and x_i .

In figure 2 the gains from trade of regions A and B are given by the sum of the areas CDP_a and P_bGF . These gains may be obtained by subtracting the areas FGX_b0 and CP_aP_bE from the area $CDOX_a$. This is given by expression (13) for the n -countries case. $\sum_i [-\chi_i(x_i)]$, in fact, gives the algebraic sum of the areas under each region's excess supply/demand function, as a positive term if the region is importing ($x_i < 0$), negative if it is exporting ($x_i > 0$). The net gains from trade are obtained by subtracting the transportation costs plus the tariff revenues minus the

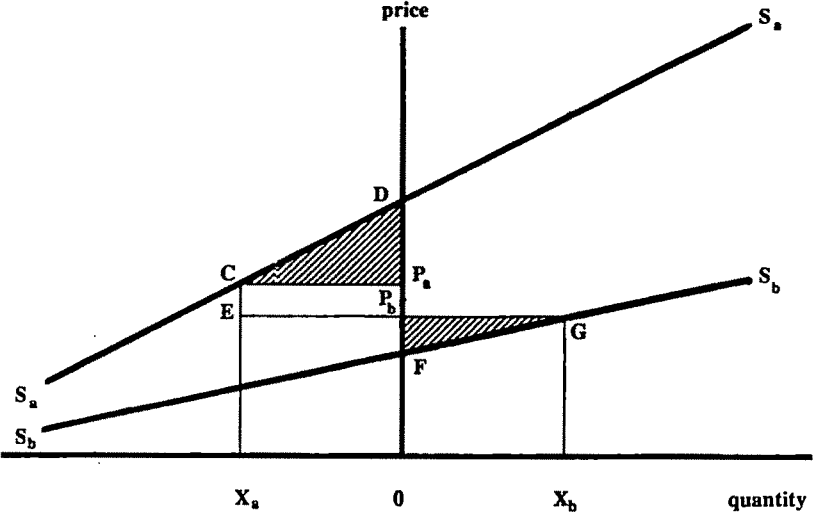

Figure 2. Two-country world trade equilibrium

subsidy expenditure (the algebraic sum of tariffs, subsidies and transportation costs is given in fig. 2 by area CP_aP_bE).

When excess demand/supply functions are used, arbitraging can no longer be constrained to not exceed domestic consumption.⁹

The problem now is stated as

$$(14) \quad \max_{x_{ij}} W,$$

subject to

$$(15) \quad \xi_i^2 \left\{ [1 - (\xi_i - 1)/-2] \sum_j x_{ji} + [(\xi_i - 1)/-2] \sum_j x_{ij} \right\} = 0, \\ i = 1, \dots, n;$$

$$(16) \quad x_i = \sum_j x_{ij} - \sum_j x_{ji}, \quad i = 1, \dots, n;$$

$$(17) \quad x_{ij} \geq 0; \quad i, j = 1, \dots, n.$$

Equilibrium prices and individual countries gains from trade are computed as

$$(18) \quad p_i = p_i(x_i^*), \quad i = 1, \dots, n;$$

$$(19) \quad W_i = [p_i(x_i^*)x_i^*] - \chi_i(x_i^*) + \sum_j (\pi_{ji}x_{ji}^*), \quad i = 1, \dots, n.$$

A Numerical Example

In this section a numerical example illustrates how the results from the proposed model compare with those which may be obtained using other spatial trade models. While the exercise provides some interesting insights about embargoes, its objective does not go beyond showing the effectiveness of the proposed model in analyzing the effects of discriminatory trade policies by explicitly investigating alternative hypotheses regarding arbitraging and cooperation by the other actors involved.

The focus is on the 1980 U.S. embargo of the USSR. It lasted from 4 January 1980 to 24 April 1981 and covered several agricultural products, including wheat, feed grains, soybeans, meat, and dairy products. The embargo was only par-

tial, because the United States fulfilled its commitment to the 1975 U.S.-USSR trade agreement allowing the export to the USSR of 8 million tons of grains in 1979/80 and 1980/81.

The embargo was motivated solely on the basis of a foreign policy concern, as a retaliation to protest the "USSR invasion of Afghanistan." The decision was based on a Central Intelligence Agency (CIA) estimate that the embargo would strongly affect meat consumption in the USSR (USDA). The CIA estimate assumed full cooperation of all other exporters and ignored the possibility of countries arbitraging. The actual short-run impact of the embargo was substantially smaller than expected. It had a very small impact, if any, on meat consumption in the USSR. The USSR strategy was essentially based on (a) replacing imports from the United States by increased imports from other sources, (b) increasing imports of substitute goods, and (c) slightly reducing its stocks.

The main data source is the comprehensive study mandated by the U.S. Congress (USDA). Consistent with the approach followed so far, only one commodity (wheat) is considered in a partial equilibrium framework. Excess supply/demand functions for twenty-seven regions are derived from base net trade positions, prices, and trade elasticities used in USDA. The transportation costs matrix expands on that used in Holland and Sharples.¹⁰ The model is short run in nature; that is, production is fixed and only consumption, stocks, and trade flows change in response to changes in prices. The model time framework is 1980, the only full year the embargo was in place. Domestic as well as trade policies have been incorporated by including price transmission elasticities in the computation of the trade price elasticities (USDA).

The objective is an a priori evaluation of the effects of a zero constraint on wheat exports from the United States to the USSR. Hence, the base solution has no constraints on the trade flows. This solution is then compared with five different scenarios in which the embargo is active and different hypotheses regarding arbitraging and the cooperation of the other countries are assumed. In the first one it is assumed that no country cooperates and arbitraging can occur; that is, the only constraint imposed is the zero constraint on the U.S.-USSR trade flow. The second scenario assumes that all the other ex-

⁹ However, in this formulation of the problem, as well as in the one based on domestic demand and supply functions, each country's arbitraging may be easily constrained not to exceed a specific amount by inserting an ad hoc constraint.

¹⁰ Detailed information regarding the excess supply/demand functions and the transportation costs matrix used are in Anania and McCalla, which can be obtained from the authors.

porters in the base scenario (Canada, the European Community, Oceania, and Argentina) agree not to increase their exports to the USSR above the pre-embargo levels. However, importers are left free to arbitrage. In the third scenario all countries are cooperating; that is, exporters agree not to increase their exports to the USSR, and importers agree not to arbitrage. The fourth and fifth scenarios differ from the second and the third, respectively, only because Argentina is now assumed not to cooperate. (In 1980 Canada, the European Community, and Oceania agreed not to increase their exports to the USSR, even if their actual level of cooperation remains questionable, while Argentina announced that it was not going to cooperate.)

Trade flows and net-trade positions in the base solution are given in table 3. In the pre-embargo scenario the United States exports 33.7 million tons of wheat, and exports to the USSR equal 5.3 million tons. The other net exporters are Canada (17.5 million tons), the European Community (9.1), Oceania (12.2), and Argentina (4.9). Major importers are Japan (5.7 million tons), East Europe (5.4), USSR (14.4), China (12.2), Egypt (5.3), and Middle East (5.3).

Under the first scenario, in which (a) the United States stops its exports to the USSR, and

(b) other countries do not cooperate (table 4), the embargo has negligible effects on the twenty-seven regions' net trade positions. USSR wheat imports from the United States are replaced by increased imports from Canada and, as a result, USSR total wheat imports decline by only 59,000 tons. The United States, in turn, made up for the embargo on its exports to USSR by (a) increasing its exports toward regions they were already exporting to, and (b) exporting 2 million tons to East Europe and half a million tons to Egypt. Essentially, if the United States imposes the embargo with no cooperation from the other market participants, the policy results in a complete failure. Net trade positions remain (almost) unchanged, and only marginal welfare losses arise from increased transportation costs due to the changes in the trade flows.

In the second scenario the U.S. embargo receives full cooperation from all the regions exporting in the base solution (Canada, EC, Argentina, and Oceania). They agree not to increase their exports to the USSR above the base solution levels. However, importers are left free to arbitrage. This scenario actually is very close to the one the United States was trying to reach in 1980. The results of this simulation (table 5) show that obtaining exporters' cooperation does

not guarantee effective results. USSR wheat imports are now predicted to decrease only by 400,000 tons. USSR import price, on the other hand, raises by \$10.48 because of increased transportation costs (table 9). The USSR substitutes for its imports from the United States thanks to arbitrage. It imports 3 and 1.8 million tons from East Europe and from the non-EC western European countries, respectively. Both regions are net importers and arbitrage increased exports from the United States (East Europe) and from Canada (other West Europe). U.S. exports decrease by only 272,000 tons, while price falls by \$1.32. World wheat trade falls only by 271,000 tons. Hence, these simulations suggest that, even if the United States had obtained co-operation from the other exporters, this would not have assured a significant impact of the embargo because of arbitraging. Arbitraging, however, was not considered a relevant issue during the policy design and implementation.

In the third scenario (table 6) all countries cooperate—exporting countries restrict their exports to the USSR not to exceed pre-embargo levels, and importing countries do not arbitrage. The embargo impact is now significant. USSR wheat imports equal only 9.090 million tons, 5.3 million tons below the pre-embargo level. If

Canada, which is the only country exporting to the USSR, does not exploit market power, then USSR import price is \$13.49 lower than the pre-embargo one (table 9). U.S. exports decrease by 2.8 million tons and the export price by \$13.69. World wheat trade decreases by 3.7 million tons. It should be noted that the United States is not the only region paying a price for the U.S. embargo. Canada's exports fall by almost 600,000 tons and its export price by U.S. \$13.49. EC, Argentina, and Oceania all experience lower exports and prices because of the increased competition from U.S. exports in their traditional markets. (The same argument is in Paddock.)

The fourth and fifth scenarios (table 7, 8) show that Argentina not cooperating was a sufficient condition to make the U.S. effort hopeless. In fact, when all exporters but Argentina are constrained to export to the USSR volumes not exceeding the pre-embargo levels, the impact of the embargo is very small. USSR imports decline only by 371,000 tons when arbitraging is allowed (and some arbitrage occurs), and by 382,000 tons when importing countries are assumed to cooperate fully.

The third scenario, in which all exporters cooperate and no arbitraging occurs, likely reflects the one assumed by the CIA when anticipating

Assuming Canada does not exercise market power.

a strong embargo impact. The fourth scenario—on which arbitraging is allowed, Canada, Oceania, and the EC keep their exports at the pre-embargo levels and Argentina does not cooperate—represents the one closest to the actual outcome.

The results of this analysis suggest that embargoes are not effective policy instruments. Rather, embargo effectiveness rests on one of the two following conditions: (a) all countries cooperate (exporters by freezing their exports to the target country, importers by not arbitraging), or (b) all exporters agree to freeze at the pre-embargo levels their exports not only to the target country but to all importing regions. Both conditions are difficult to achieve.

Finally, if all exporters agree to cooperate, they share part of the cost of the embargo because the embargo imposing country's exports will now displace part of their pre-embargo exports. This implies that asking for cooperation in an embargo scheme should be supported by either a reimbursement for the costs or by the guarantee that the embargo-imposing country's exports would not exceed the pre-embargo level minus

the volume exported to the country the embargo is imposed on.¹¹

¹¹ A second numerical example providing additional evidence on how the model proposed performs compared with NLP and VS models is in Anania and McCalla. This example addresses the hypothetical *ex ante* analysis of the granting of a preferential tariff reduction. Four different solutions are discussed. In the first solution—obtained using the QP and the VS models based on domestic demand and supply functions and the model proposed in this paper, all assuming, implicitly or explicitly, that arbitraging is allowed but constrained not to exceed domestic consumption—one of the beneficiary countries switches from being an importer to being an exporter due to the tariff preference it is granted. Arbitraging occurs and the constraint on its volume is binding. The second solution has been obtained using the QP model based on excess demand and supply functions, and the model proposed leaving arbitraging unconstrained. The nonpreferred exporter increases its exports, completely bypassing the discriminatory tariff. Its exports to the preference granting country are rerouted through one of the countries benefiting of the preferential treatment. The welfare of the preferred countries is lower than that occurring under a non-discriminatory tariff. The third and the fourth solutions are obtained using the model proposed imposing no arbitraging and assuming two alternative hypotheses regarding the beneficiary countries' behavior: that they collude, and that each of them makes its choice between being an exporter and being an importer on the basis of its own welfare only. In these two scenarios the preferred countries reach the highest welfare, and the most efficient policy outcomes (in terms of the welfare the preference-granting country has to give up in order to induce a one-unit increase in the welfare of the beneficiary countries) are obtained.

Conclusions

Arbitraging is an important issue in discriminatory trade policy design and implementation. It may turn discriminatory trade policies into ineffective and very costly policy options. Preventing arbitraging is a very difficult task.

In this paper a simple model has been proposed to analyze discriminatory trade policies. It improves upon commonly used spatial trade models by allowing countries to move from one side of the market to the other as equilibrium prices change, and it allows researchers to properly specify their own assumptions about arbitraging and/or to obtain different solutions as a function of different policy constraints or different levels of effectiveness in enforcing such constraints.

The example presented, focusing on the 1980 U.S. embargo of the USSR, provides evidence on the importance of carefully considering arbitraging in the design and implementation of discriminatory trade policies. Different hypotheses regarding arbitraging (or, more often, the apparently "neutral" choice among alternative models thought to be equivalent) may yield contrasting forecasts of the trade policy impact.

Dynamic Adjustment in the Japanese Livestock Industry Under Beef Import Liberalization

Thomas I. Wahl, Dermot J. Hayes, and Gary W. Williams

Dynamic adjustment of Japanese livestock markets is analyzed under two alternative import policies: the 1988 Japanese Beef Market Access Agreement (BMAA) and complete liberalization of Japanese beef import policies. Modeling problems associated with these policies include the change from a quota to a tariff, the incorporation of a meat demand system derived from utility-maximizing behavior into a livestock policy model, complementarity, and changes in the degree of producer supply responsiveness under alternative policies. An econometric model of the Japanese livestock industry is used to simulate and compare the impacts of the two policies from 1988 through 1997.

Key words: trade liberalization.

Japanese beef producers have been protected from the effects of world markets by government price supports and trade policies since the early 1960s. Japanese beef import suppliers, principally the United States and Australia, have made numerous bilateral and multilateral attempts to liberalize the Japanese market. At the same time, the Japanese government has resisted greater access to its beef markets, preferring relatively small increases in the quota both to appease U.S. interests and to minimize opposition from the politically powerful domestic beef producers. Bilateral negotiations between the United States and Japan in 1988, however, resulted in the Beef Market Access Agreement (BMAA), which was intended to liberalize the Japanese beef market substantially over a six-year period.

The primary purpose of this paper is to analyze the likely dynamic impacts of the recent Japanese beef import agreement upon Japanese livestock supply, meat demand, and beef imports. The results are compared with the effects of continuing a slowly increasing beef import quota, as existed under the previous agreement, and complete liberalization of beef imports. The paper also provides some insights into the gen-

eral analysis of markets under a policy-induced structural change. An econometric simulation model of the Japanese livestock and meat industry is utilized to analyze the likely effects of the alternative policies. A number of associated modeling problems are addressed including the incorporation of an almost ideal demand system (AIDS) for meat into a more complete dynamic model of livestock and meat supply and demand, a shift from an import quota to a tariff as required under the BMAA in 1991, and the out-of-sample price responsiveness of livestock producers.

Following a historical overview of the Japanese livestock industry and policies, a model of the Japanese livestock sector is discussed. Next, the results of simulating the liberalization of beef imports are presented. Finally, some research and policy implications are drawn.

The Japanese Livestock Industry and Policy

The evolution of Japan's political economy following World War II has been the primary motivating force behind the generally protectionist Japanese agricultural policies. Concerns about food security have given agricultural producers a tremendous influence upon Japan's food policies (Longworth). Rural heritages, the electoral system, and the Japanese agricultural cooperatives movement have reinforced the political base

Journal Paper No. J-13379 of the Iowa Agriculture and Home Economics Experiment Station, Project No. 2835.

of farmers. Immediately following World War II, the majority of the population lived and worked on small farms. But as Japan's economy recovered and grew, the population began to shift toward urban centers. Despite the shift in population, representation in the Diet (the Japanese Congress) has been not reapportioned. Consequently, the political influence of the rural districts has increased disproportionately, fostering legislation designed to protect the interests of farmers and agriculturally related industries and to maintain food self-sufficiency levels.

In the 1960s, Japanese self-sufficiency ratios for beef, pork, and chicken meat were all above 90%. By 1988, self-sufficiency ratios for these three meats had dropped to 45%, 80%, and 85%, respectively. Japanese domestic beef supplies come from the native Japanese cattle (Wagyu) herd and the domestic dairy cattle herd. Wagyu cattle have traditionally been fed for long periods (up to 30 months) to produce a highly marbled beef that sells for a substantial premium over the less marbled dairy beef.

Thirty-five percent of the beef from Japanese dairy breeds usually grades as medium and 44% usually grades as common. The typical U.S. choice grade grain-fed beef generally falls between these two grades. Grass-fed beef is most nearly equivalent to the common grade. It is unusual for either dairy or imported beef to make the supreme, superior, or excellent grades that are generally reserved for beef from the Wagyu breed (Miyazaki). There is some evidence that Wagyu beef can be viewed as a separate type of meat and not as a perfect substitute for either dairy or imported beef (Hayes, Wahl, and Williams).

The livestock industry in Japan has had one of the highest levels of protection in the world. Historically, an import quota has been the main policy tool to support the domestic cattle industry and encourage beef production. Through the complicated import quota structure, the government has attempted to maintain the established domestic beef target prices. Then, through a fine-tuning mechanism of purchasing and storing or releasing frozen beef from stocks (the beef price stabilization scheme), the government has stabilized the domestic beef price around the target within a politically and socially acceptable range (the upper and lower stabilization prices). The rapidly increasing demand for beef in Japan has forced the government to allow imports to increase over time to keep prices from increasing significantly above the established stabilization range. As a consequence, Japanese domestic beef

prices have been higher and more stable than otherwise might have been the case.

The Japanese dairy industry is protected by a milk price support program designed to ensure a stable, sufficient supply of milk. The pork industry is protected from world competition by a variable import levy and an ad valorem import tariff. The chicken meat industry is relatively unprotected, but it benefits from the substitution effects of the other policies.

The Beef Market Access Agreement

In June 1988, the Japanese signed the BMAA and agreed to begin a phased reduction of their beef import restrictions. The agreement calls for a 60,000 metric ton annual increase in the import quota during the first three years; i.e., the transitional phase of the agreement beginning in 1988. In the post-transitional phase, however, the quota will be removed completely in 1991 and will be replaced by a 70% tariff.¹ The tariff is to be reduced to 60% in 1992 and to 50% in 1993 (table 1).

Prior to the BMAA, the beef import quota consisted of a general quota and a smaller special quota. Only 10% of the general quota was allocated directly to private traders. The Livestock Industry Promotion Corporation (LIPC) controlled the remainder of the general quota, which was allocated to certain Japanese trading companies through both the simultaneous buy/sell (SBS) system and the tender system. The SBS system allowed Japanese buyers to import beef directly from foreign beef exporters. As shown in table 1, the SBS portion of the LIPC quota was relatively small (10%) in comparison to the tender portion (90%). However, during the transitional phase of the BMAA, the majority of the increase in the global quota has occurred in the SBS portion of the LIPC quota.

The tender portion of the LIPC quota was designed to allow the LIPC to dictate the quality and origin of Japanese beef imports. The LIPC tendered licenses for imports of specific grades of specific beef cuts from specific markets. Licensed trading companies would then purchase the beef from exporters in those specific markets. The BMAA called for a phaseout of LIPC involvement in beef imports in 1990.

¹ Additional safeguards for the Japanese allow for an additional 25% tariff in any year of the post-transitional period in which beef imports increase by 20% or more over the previous year.

Table 1. Japanese Beef Import Quota Levels Under the BMAA (metric tons)

Quota	Transitional Phase				Post-Transitional Phase		
	1987	1988	1989	1990	1991	1992	1993
Global	214,000	274,000	334,000	394,000	472,000 ^a	667,360 ^a	680,832 ^a
Special	20,000	25,000	27,000	30,000	0	0	0
General	194,000	249,000	307,000	364,000	0	0	0
Private	19,000	24,000	307,000	36,400	0	0	0
LIPC ^b	174,600	224,100	276,300	327,000	0	0	0
Tender	157,140	156,870	151,965	151,040	0	0	0
SBS ^c	17,460	67,230	124,335	196,560	0	0	0
Tariff (%)	0.25	0.25	0.25	0.25	0.70	0.60	0.50

^a Level of beef imports that invokes an additional 25% tariff as a safeguard measure.

^b LIPC is Livestock Industry Promotion Corporation.

^c SBS is simultaneous buy/sell.

Effects of the BMAA

Although elimination of beef import restrictions could put pressure on the domestic Japanese cattle industry as well as on the domestic hog, poultry, and fish industries, the extent of the pressure depends upon the degree to which beef imports increase, the response of Japanese cattle producers to expected price changes, the degree of substitutability among meats (including fish) in Japanese consumption, and the policy response of the Japanese government.

If the annual increases in the quota during the transitional period of the BMAA are large enough in comparison to the annual growth in Japanese beef demand over that period, imports might not increase to the higher quota levels and prices in Japan would fall toward world market levels. Even if imports reach the quota level during that period, beef imports could decline during the post-transitional period of the BMAA when the quota is dismantled and the import tariff is implemented. On one hand, if the tariff to be implemented is greater than the tariff equivalent of the quota (i.e., the percentage difference between the domestic and the world prices of import-quality beef), then imports will decline when the tariff is imposed. On the other hand, if the tariff is less than the tariff equivalent of the quota, imports will increase. Thus, whether Japanese beef imports increase or decrease in 1991 from the quota level at the end of the first three years of the BMAA depends largely upon the tariff equivalent of the quota in 1990. If the internal price is more than 70% above the world price of beef in 1990, then Japanese beef imports will increase in 1991. Otherwise, the imposition of the 70% tariff in 1991 could lead to a decline in imports.

The Japanese Livestock Industry Model

The fifty-one-equation model of the Japanese livestock industry used for the analysis of Japanese beef import policy contains three simultaneous sectors: the Wagyu cattle, dairy cattle and beef cattle sector; the hog and pork sector and the chicken meat sector.² The cattle and hog sectors contain two main components: (a) live animal supply (breeding herd, slaughter livestock inventories, animals raised, and imports) and slaughter demand and (b) meat supply (production and imports) and meat demand (consumption). The chicken meat sector contains only meat supply (production and imports) and meat demand (consumption). The livestock supply and demand system is estimated by using three-stage least squares (3SLS), and the meat supply and demand system is estimated by using iterated three-stage least squares (IT3SLS).

Japanese Livestock Supply and Demand

The biological restrictions that are inherent in livestock production are incorporated into the live animal supply and demand component. As a result of these biological restrictions, the source of new animals (i.e., the breeding-herd inventories) "drives" the live animal supply components of the model because future production is determined by current decisions about breeding-herd size. For example, the number of animals born in a given year depends upon the size of beginning breeding-herd inventories. Ending inventories of feeder animals depend upon the

² See Wahl for details of the model, estimation procedures, validation: statistics, and the data used.

number of animals born in the current and previous years. And, because the time from birth to slaughter is constant in an annual model, production in the current period is determined by breeding-herd decisions made in previous periods.

In general, these producer decisions can be represented by the following standard theoretical breeding-herd inventory model for cattle:

$$(1) \quad H_t^* = f(\Pi_{t+1}^e, Z_t),$$

where H_t^* is the desired breeding-herd size at the end of period t , Π_{t+1}^e represents the expected profitability of raising cattle in the following period (the expected cattle price deflated by the expected feed price in period $t + 1$), and Z_t represents other variables, such as technical change, that may affect the desired ending herd size in period t .

A standard form of (1) for estimation can be derived by assuming a partial adjustment framework for inventories and adaptive price expectations:

$$(2) \quad H_t - H_{t-1} = \tau(H_t^* - H_{t-1}), \text{ and}$$

$$(3) \quad \Pi_{t+1}^e - \Pi_t^e = \theta(\Pi_t - \Pi_t^e),$$

where τ is the coefficient of adjustment, θ is the coefficient of expectation, and $0 \leq \tau, \theta \leq 1$. Equation (2) suggests that, primarily because of biological restrictions and the cost of adjustment, changes in breeding-herd size take time; i.e., the breeding herd cannot adjust fully in one year to the long-run desired level. Equation (3) assumes that the change in expected profit in period $t + 1$ is proportional to the current error in forecasting.

Assuming a linear form of (1) and then substituting both (2) and (3) into that equation yields the following breeding inventory model for estimation:

$$(4) \quad H_t = \alpha_0 + \alpha_1 \Pi_t + \alpha_2 H_{t-1} - \alpha_2 H_{t-2} + \alpha_4 Z_t - \alpha_5 Z_{t-1},$$

where

$$\alpha_0 = \tau \theta a,$$

$$\alpha_1 = \tau \theta b,$$

$$\alpha_2 = [(1 - \tau) + (1 - \theta)],$$

$$\alpha_3 = (1 - \tau)(1 - \theta),$$

$$\alpha_4 = \tau c,$$

$$\alpha_5 = \tau(1 - \theta)c.$$

Also, a is the intercept, and b and c are the coefficients of the variables in the linear form of (1); all other variables are as previously defined. The value of θ can be calculated directly from the estimated coefficients of equation (4). The remaining parameters (τ , a , b , and c) can be derived by a procedure suggested by Maddala, given a value for θ .

Because the Japanese government has historically maintained price stabilization bands by using import restrictions and buy/sell programs, producers may consider changes in the government support price to be permanent indicators of future price movements. Movements in market prices outside the price stabilization band have been considered to be only temporary indicators of future price movements. Consequently, Π_t in (4) includes both the market price and the announced government support price, which implicitly assumes that producers form a composite forecast by using both the market and government prices (Granger and Newbold, Hayes and Wahl).

Assuming the framework of (4) for breeding-herd inventories, the live animal supply and demand system for a given livestock type i (Wagyu cattle, dairy cattle, or hogs) is modeled by following the specifications of (5) through (8). Unless otherwise noted, all variables are subscripted by t (year).

$$(5) \quad H_i = \alpha_{i1} + \alpha_{i2} P_i^L / K_i + \alpha_{i3} H_{i,t-1} + \alpha_{i4} H_{i,t-2} + \alpha_{i5} Z_i + \alpha_{i6} Z_{i,t-1} + \alpha_{i7} G_i / K_i,$$

$$(6) \quad R_i = q_i H_{i,t-1},$$

$$(7) \quad F_i = \lambda_{i1} + \lambda_{i2} R_i + \lambda_{i3} R_{i,t-1},$$

$$(8) \quad L_i = H_{i,t-1} - H_i + R_i + F_i - F_{i,t-1}.$$

Endogenous variables are H_i , R_i , F_i , L_i ; H_i is the ending breeding inventory of type i (i = Wagyu cattle, dairy cattle, or hogs); P_i^L is the price of livestock type i ; K_i is the cost of feed for i ; Z_i is the exogenous variable affecting breeding-herd size decisions for livestock type i ; G_i is the government support price of i ; R_i is the offspring of i raised; q_i is the annual birth rate of i ; F_i is the ending feeder inventories of i ; L_i is the slaughter of livestock type i ; and α and λ are estimated parameters.

The production cycle for chickens is only five to six weeks. Consequently, chicken inventory and slaughter equations are less meaningful in an annual model than they are in shorter time frame models. Production changes in response to price changes can occur within such a short time interval that counterintuitive price respon-

siveness may be estimated when using annual data. Thus, live chicken supply and demand equations are not included in the model. However, chicken meat supply and consumption components are included and discussed in the following section.

Japanese Meat Supply and Demand

A reduction in the protection of Japanese beef production would have consequences beyond those for the beef sector alone. Changes in the price and quantity of beef demanded in a given period would affect the demand for other meats, which in turn would alter the prices and, therefore, the supply of other meats in subsequent periods. The dynamic supply adjustments occurring in these other livestock markets would produce feedback effects in the beef market. These supply and feedback effects are usually ignored in most demand analyses, including demand system estimation, but are of crucial importance when the likely magnitude of the price changes and the period over which such changes are expected to occur are relatively large.

The reliability of the analytical conclusions also requires internal consistency in the empirical model. For example, the sum of predicted consumer expenditures on individual meat items should equal the predicted expenditures on all meats. At the same time, the income-compensated effect of a change in beef prices on pork demand should equal the income-compensated effect of a change in pork prices on beef demand. Consequently, the meat demand subsystem in the model should conform to the theoretical restrictions of adding up, homogeneity, and Slutsky symmetry.

Incorporating these theoretical restrictions requires a systems approach to demand estimation. The choice of the aggregation level is also of concern. Ideally, a system including the entire food sector, or even all goods, should be specified and estimated. Because data limitations make including the entire food sector impractical if not impossible, the meats group (including fish) is assumed to be separable from other expenditure groups in this study.

The meat expenditure system used in the model follows the linear approximation of the AIDS (LA/AIDS) specification of Deaton and Muellbauer. Consequently, the budgetary share (W) allocated to the i th meat item in the model is estimated as follows:

$$(9) \quad W_i = \gamma_i + \sum_j \gamma_{ij} \ln P_j + \beta_i \ln E/P,$$

where P_j is the price of good j , E is the per capita expenditures on all five meats, and P is a suitable price index. For P , Deaton and Muellbauer suggest the use of Stone's index (defined as $\ln P = \sum W_i \ln P_i$).

The LA/AIDS places no restrictions on cross price elasticities. Although this lack of restrictions may be desirable from a theoretical viewpoint, utilizing a model with elasticities that are contrary to a priori expectations for policy simulation analysis could lead to counterintuitive results. In this sense, the demand system would not be well behaved. In fact, the estimated elasticities (with homogeneity and symmetry imposed) exhibit complementarity between import-quality beef and chicken meat and between pork and chicken meat. These results would lead to a counterintuitive increase in the simulated level of chicken meat consumption in Japan, for example, given a decline in the price of import-quality beef from import liberalization. The approach taken here was to impose net substitutability on the model by using a Bayesian procedure developed by Geweke as implemented by Hayes, Wahl, and Williams.

To implement this procedure, the estimated parameter vector and variance-covariance matrix of the demand system are used to generate a multivariate normal distribution. Repeated draws from this distribution are then made, testing each vector for net substitutability. The posterior distribution is formed from the parameter vectors that satisfy the inequality restriction:

$$(10) \quad \gamma_{ij} \geq -W_j \cdot W_i.$$

The mean of this posterior distribution will then satisfy net substitutability (see Hayes, Wahl, and Williams for more detail).

The price and expenditure elasticities of the Japanese demand system used in the model (presented in table 2) are Hicksian measures with Slutsky symmetry, homogeneity, and net substitutability among meats imposed upon the estimated IT3SLS coefficients. All own-price elasticities are negative, and all compensated cross-price elasticities are positive. The own-price elasticities are relatively large, especially for beef and imply (*ceteris paribus*) that any reduction in the Japanese beef import barrier would lead to a large increase in the quantity demanded of import-quality beef.³ The estimated expenditure

³ The term import-quality beef is used to refer to the aggregate of imported beef and domestic dairy beef.

Table 2. Japanese Meat Demand and Expenditure Elasticities

Price or Expenditure	Wagyu	IQ Beef ^a	Pork	Chicken	Fish
Wagyu	-2.48	0.44	0.71	0.42	0.90
IQ Beef	0.26	-0.98	0.22	0.04	0.46
Pork	0.24	0.12	-0.73	0.05	0.31
Chicken	0.19	0.03	0.07	-0.91	0.62
Fish	0.08	0.07	0.08	0.12	-0.35
Expenditure	0.75	1.51	0.98	1.15	0.92

Note: All elasticities are Hicksian measures calculated from iterated three-stage least squares (IT3SLS) estimates with Slutsky symmetry, homogeneity, and net substitutability imposed. These results differ slightly from those presented in Hayes, Wahl, and Williams in that they use an iterated seemingly unrelated regressions (ITSUR) estimator.

^a IQ beef is import-quality beef, the aggregate of Japanese dairy beef and imported beef.

elasticities indicate that both Wagyu and import-quality beef are luxury goods in Japan. The expenditure elasticity of demand for import-quality beef is also greater than is that for Wagyu beef. This result is somewhat surprising because Wagyu beef is more expensive in Japan than is import-quality beef.

Integrating the Supply and Demand Systems

The full Japanese livestock industry model combines the meat expenditure system with the supply dynamics for Wagyu cattle and beef (*g*), dairy cattle and import-quality beef (*d*), hogs and pork (*p*), chicken meat (*c*), and fish (*f*). As a large-country representation of the industry, the model incorporates Japanese meat prices and import policies. The live animal component of the model consists of equations (5) through (8) for Wagyu cattle, dairy cattle, and hogs. A conceptual representation of the meat component of the model is represented by equations (11) through (25). The full model, estimated parameters, and validation statistics for the full Japanese livestock industry model are available from the authors.

$$(11) \quad S_i = bL_i \quad (\text{for } i = g, d, p)$$

$$(12) \quad S_c = S_c(P_c^m, T)$$

$$(13) \quad D_i = E_i/P_i^m \quad (\text{for } i = g, d, p, c, f)$$

$$(14) \quad E_i = W_i E \quad (\text{for } i = p, c, f)$$

$$(15) \quad E_i = P_i D_i \quad (\text{for } i = g, d)$$

$$(16) \quad W_i = \gamma_i + \sum_j \gamma_{ij} \ln P_j^m + \beta_i \ln(E/P) \quad (\text{for } i, j = g, d, p, c, f)$$

$$(17) \quad \ln P = \sum_i W_i \ln P_i^m \quad (\text{for } i = g, d, p, c, f)$$

$$(18) \quad P_c^m = P_c(P_c^w)$$

$$(19) \quad V_p = P_p^m - P_p^w$$

$$(20) \quad C_i = D_i \cdot N \quad (\text{for } i = g, d, p, c, f)$$

$$(21) \quad C_g = S_g$$

$$(22) \quad C_d = S_d + \bar{M}_d$$

$$(23) \quad M_i^p = C_i - S_i \quad (\text{for } i = p, c)$$

$$(24) \quad M_i^s = M_i^s(P_i^w) \quad (\text{for } i = d, p, c)$$

$$(25) \quad M_i^s = M_i^p \quad (\text{for } i = d, p, c)$$

where *b* is average slaughter weight;

C_i, total consumption of meat *i* (*);

D_i, per capita consumption of meat *i* (*);

E_i, per capita expenditure on meat *i* (*);

E, per capita consumer expenditure on all meats (*);

L_i, slaughter of livestock type *i* (*i* = *g*, *d*, *p*) (*);

\bar{M}_d , import quota on beef (import-quality);

M_i^s, total import supply for meat *i* (*i* = *d*, *p*, *c*) (*);

M_i^p, total import demand for meat *i* (*i* = *p*, *c*) (*);

P_i^m, domestic price of meat *i* (*i* = *g*, *d*, *c*) (*);

P_i^w, world price of meat *i* (*i* = *d*, *p*, *c*) in domestic currency (*);

P_p^m, fixed support price of pork;

P, meat price index (*);

S_i, domestic supply of meat *i* (*);

S_c , domestic supply of chicken meat (*);
 T , time trend or other shift variables affecting annual chicken meat supply;
 V_F , pork variable levy (*);
 W_i , expenditure share of meat i (*);
 N , Japanese population; and
 β, γ , estimated parameters.

The endogenous variables in the system are marked with an asterisk (*) following the definition of each. Livestock-meat price margin equations link the live animal and meat components of the model [$P_i^L = P_i^L(P_i^m)$ for $i = g, d, p$].

Wagyu beef is modeled as a nontraded commodity. Thus, Wagyu beef is affected by beef imports only through the cross-price effects. Imported beef is treated as the equivalent of dairy beef. Pork is subject to a variable import levy, and chicken is free of import restrictions. The domestic prices of meat (P_i^m) are determined by the interaction of domestic meat supply (S_i) and demand (C_i). The prices of beef, pork, and chicken meat supplied to Japan by the world market (P_i^w) are determined by the excess supplies of each meat facing Japan (M_i^s) and the Japanese import demand for each (M_i^D).

Data Sources

The expenditure and price data used to estimate the parameters of the Japanese livestock industry model presented in the previous section are taken from various yearbooks and reports published by the Japanese Ministry of Agriculture, Forestry, and Fisheries (MAFF). These publications include various issues of *Statistical Yearbook*, *Statistics of Meat Marketing*, *Meat Statistics, in Japan*, *Monthly Statistics of Agriculture, Forestry, and Fisheries*, and the *Annual Report on the Family Income and Expenditure Survey*. Expenditures are calculated as the product of price and disappearance (retail basis) for each meat type. Disappearance for Wagyu beef, import-quality beef, pork, and chicken meat are calculated as the sum of production and imports, the data for which are available from the *Statistical Yearbook*. Data for consumer, wholesale, and producer price indexes, family income, retail fish disappearance, and household family size are also available from the *Statistical Yearbook*. Inventory data for live animals, slaughter numbers, slaughter weights, prices paid to farmers, wholesale prices, and wholesale-to-retail conversion factors are also from the *Statistical Yearbook*. Retail prices for pork and

chicken meat are from *Meat Statistics in Japan*. Retail fish price, from the *Annual Report on the Family Income and Expenditure Survey*, is an average of fresh and salted fish price series weighted by the disappearance of each.

Although a retail beef price is available in the *Meat Statistics in Japan*, individual retail prices for Wagyu and dairy beef are not published. Retail Wagyu and dairy beef prices are calculated by multiplying the respective wholesale prices, available in *Statistics of Meat Marketing* and *Meat Statistics in Japan*, by 2.1156. This coefficient is the average ratio of total retail beef expenditures to the sum of wholesale Wagyu beef expenditures and wholesale dairy beef expenditures.

Beef Import Liberalization

To analyze the effects of switching from a quota (i.e., exogenous imports) to a tariff (i.e., endogenous imports) under the BMAA, a series of conditional statements was added to the model to allow beef imports to fluctuate at or below (but not to exceed) the established quota level during the transitional period of the agreement. During the post-transitional period, beef imports are endogenously determined by supply and demand, which was accomplished by normalizing (23) on beef imports and adding an international price linkage equation that included the tariff (τ) to the model:

$$(26) \quad F_d^m = P_d^w(1 + \tau).$$

Beginning in 1991, the model automatically switches from a quota to the tariff specification, with the tariff set at the BMAA levels. If beef imports do not reach the quota level in any year before 1991, however, the model switches to the tariff specification in that year with the 25% tariff currently in place as called for in the agreement.

To allow for changes in the degree of producer price responsiveness following liberalization, the relative weights in the composite producer price forecast used in (5) shift to account for the discontinuation of the government prices. The weight on the government price is reduced to zero, and the weight on the market price is increased to one. For the Wagyu sector, the consequences are an increase in the elasticity of the breeding herd with respect to the market price from 0.008 to 0.10. The elasticity with respect to the market price in the dairy breeding-herd equation increases from 0.047 to 0.14.

Two alternative policies are also considered to provide comparison with the BMAA: (a) complete, immediate liberalization in 1988 and (b) continuation of the 1984 agreement to allow quota increases of only 9,000 metric tons per year. These two alternatives represent the likely upper and lower limits, respectively, of the beef import liberalization effects of the BMAA on the Japanese livestock industry. Complete liberalization is modeled in the same manner as is the BMAA during the post-transitional phase except that the tariff is set to zero for 1988 through 1997. The continuing quota simulation, on the other hand, assumes that the beef import policy prior to the BMAA remains in place. The quota is increased by 9,000 metric tons per year and the beef support prices are set at their 1987 levels. This quota policy is modeled in the same manner as that of the transitional period of the BMAA except that the quota is allowed to increase by only 9,000 metric tons per year through 1997.

Simulation Results

The simulation results suggest that, under the BMAA, Japanese beef imports will reach 394,000 metric tons by 1990, fulfilling the quota, and then increase by 263,000 metric tons in 1991 as a result of the shift to an import tariff (fig.

1).⁴ Beef imports under the BMAA are projected to reach 1.2 million metric tons by 1997. The substantial increase after 1990 in Japanese beef imports represents an opportunity for U.S., Canadian, Australian, and New Zealand beef exporters to significantly increase exports to Japan.

Complete liberalization of beef imports pushes imports to nearly 1.5 million metric tons in 1988 and to over 2 million metric tons by 1997 because of the increased demand for beef by consumers at the substantially lower world beef prices. In the continuing quota simulation, however, beef imports reach only about 300,000 metric tons in 1997.

The Japanese dairy steer carcass price, which also represents the price of imported beef in the domestic market in this model, is directly affected by the alternative import policies. Under the complete liberalization policy, dairy steer carcass price drops dramatically (by almost 68% in the first year) and remains at about that level for the remainder of the forecast period (fig. 2). Under the BMAA, dairy steer carcass price drops somewhat during the transition from a quota to a tariff in 1990–91 and then drops gradually until 1994, after which the tariff is assumed to remain at 50%.

⁴ The predicted increase in beef imports in 1991 appears to be relatively large. In reality, it is likely that infrastructural constraints and the reticence of consumers to alter expenditure patterns may shift some of the additional imports to later years.

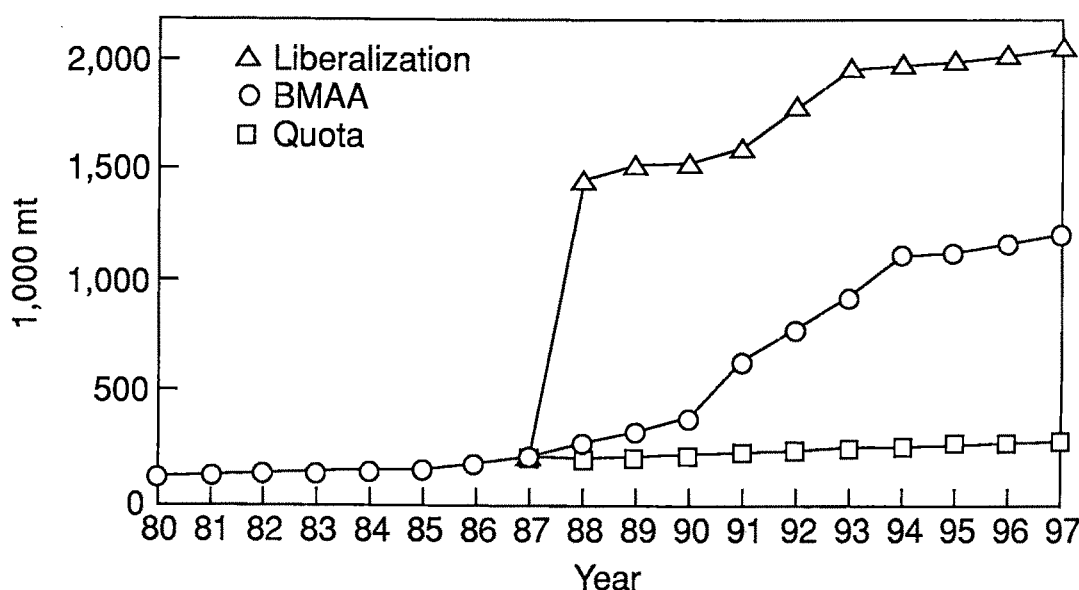

Figure 1. Beef import levels under complete liberalization, the BMAA, and an import quota

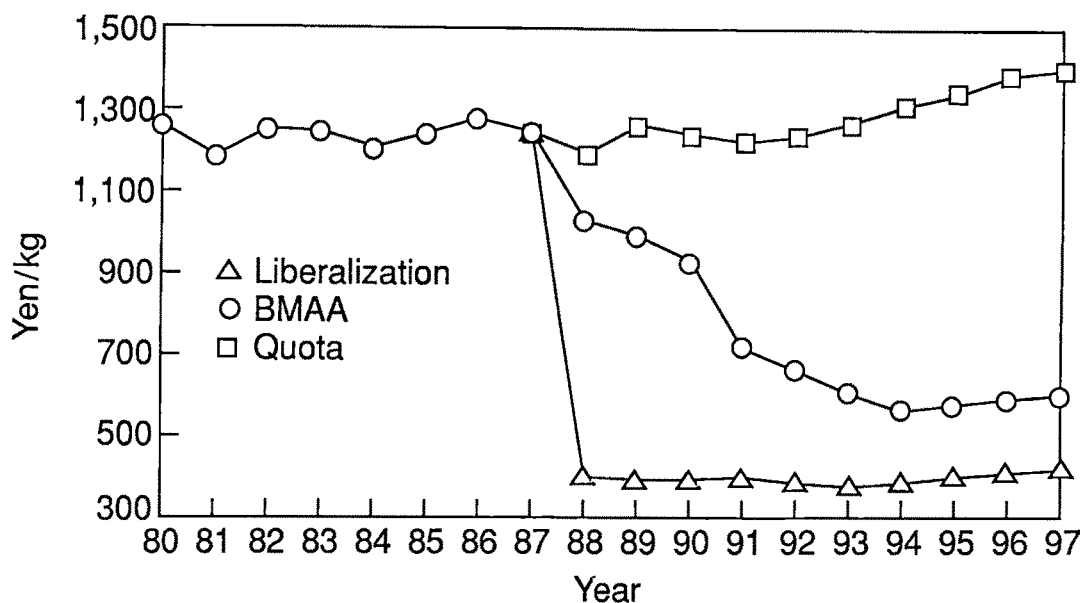

Figure 2. Dairy steer carcass price under complete liberalization, the BMAA, and an import quota

Wagyu steer carcass price (not shown) is affected by the changes in beef import policies only through cross-price effects with the other meats. Under complete liberalization, Wagyu steer carcass price drops by 19% from 1987 to 1988, compared to the 68% drop in dairy steer carcass price. Under the BMAA, Wagyu steer carcass price decreases by less than 4.5% below quota levels until 1990. After 1990, BMAA levels of Wagyu steer carcass price remain about 10% below quota levels.

The Wagyu breeding herd is relatively unaffected by either the BMAA or complete liberalization, falling below projected continuing quota levels by 11% in 1991 and by 5% in 1997 (fig. 3). Initially, the Wagyu breeding herd falls below continuing quota levels under the BMAA and complete liberalization. After 1990, however, the herd rebuilds and follows the same general cycle as the quota. The increase in the breeding herd level after 1988 under the continuing quota results from assumed decreases in feed costs that result from lower grain prices and exchange rates.

Under pressure of growing imports, the dairy cattle breeding herd decreases continuously through the end of the period under the BMAA (fig. 4). Under the continuing quota simulation, however, the dairy cattle breeding herd increases until 1992 because of predicted lower feed costs and continued high milk prices and

then declines gradually until the end of the forecast period. Under complete liberalization, the dairy cattle breeding herd decreases more rapidly than under the BMAA. Nevertheless, by 1997 the complete liberalization level is less than 6% below the BMAA result.

The impact of the alternative import policies on beef production is shown in figures 5 and 6. Wagyu beef supply is nearly equal in the three scenarios by 1997, with little deviation in the period before 1997. The implication is that the BMAA will likely lead to about the same result for the Japanese beef industry as a more immediate, complete liberalization would have, albeit more slowly. Dairy beef supply, on the other hand, is 19% lower under the BMAA and 31% lower under complete liberalization than is the case under the continuing quota scenario by 1997.

Table 3 presents projected dairy beef production, beef imports, and import-quality beef consumption for 1988, 1991, and 1997. Projected per capita consumption for import-quality beef and Wagyu beef and total beef consumption are also presented for comparison. The results suggest that per capita disappearance of import-quality beef under the BMAA could more than double by 1997, whereas Wagyu beef disappearance will likely change little.

The carcass price of hogs changes relatively little over the 1988 to 1997 period under all the policy alternatives because pork import policies

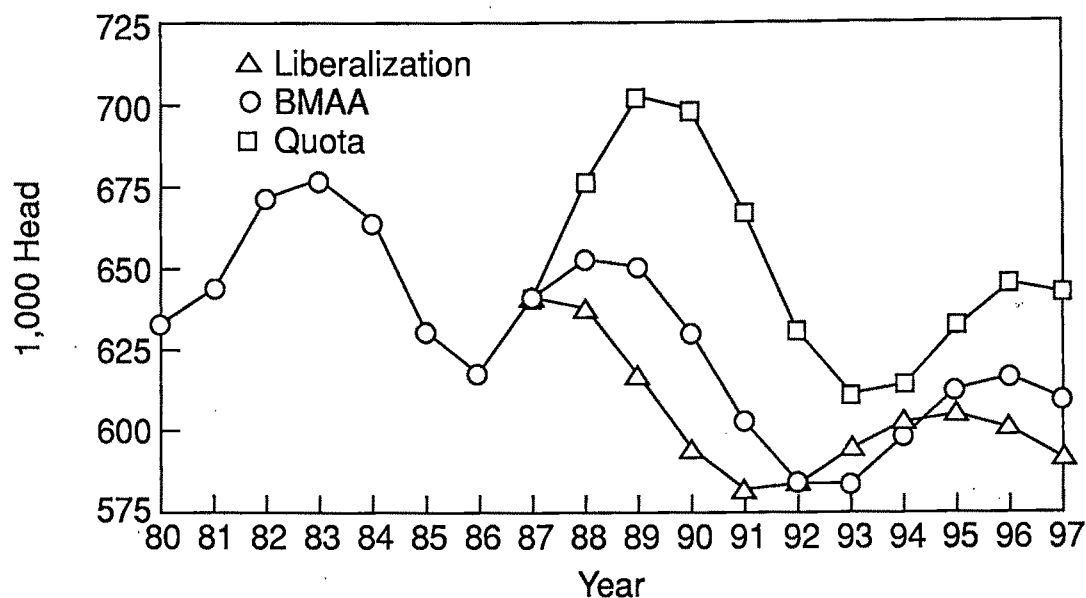

Figure 3. Wagyu cattle breeding-herd ending inventories under complete liberalization, the BMAA, and an import quota

are assumed to remain in place.⁵ Because the changes in hog prices are relatively small, the hog breeding-herd inventory, pork supply, and pork consumption also change little.

Chicken meat supply is projected to increase

⁵ For a discussion of the Japanese pork trade, see Pieri, Meilke, and MacAulay.

at a steady rate under the quota and to remain virtually unchanged under complete liberalization and the BMAA. Chicken meat imports and disappearance under either scenario remain almost unchanged from the levels under the quota. This relative lack of responsiveness to changes in beef import policy results from the low cross-price elasticities in the meat demand system. The

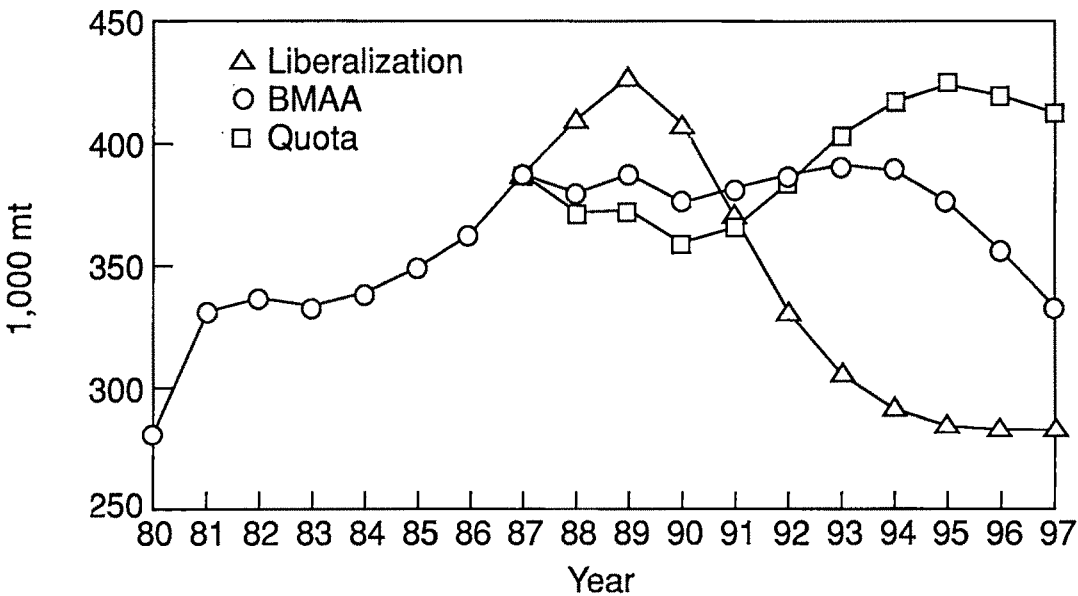

Figure 6. Dairy beef supply under complete liberalization, the BMAA, and an import quota

retail price of chicken meat changes little over the period under the alternative policies.

Sensitivity Analysis

Simulation of the alternative import policy regimes requires a number of assumptions on model

structure and exogenous variables. Two particularly crucial assumptions with significant potential to affect the simulation results involve (a) measuring the tariff equivalent of the current beef import quota and (b) the predicted rate of growth of total consumer expenditures on meat.

Measurement of the price wedge between the domestic and imported beef price is crucial when

Table 3. Projected Japanese Beef Production, Imports, and Consumption for 1988, 1991, and 1997 Under Alternative Beef Import Policies

IQ beef is import-quality beef, the aggregate of Japanese dairy beef and imported beef.

calculating the tariff equivalent of the quota because the magnitude of the price drop imposed under complete liberalization and during the post-transitional phase of the BMAA will have a significant effect on the simulated results. If the rice wedge used to calculate the tariff equivalent is artificially small, understated tariff equivalents will be calculated, and misleading policy implications may result. The appropriate order price to use when calculating the tariff equivalent is the central issue. Unfortunately, accurate historical observations of the border price of beef in Japan are difficult to obtain because the Japanese import several different cuts and

qualities of beef. The Japanese have tended to import more of the high-quality middle cuts to maximize their quota rents. Consequently, the average import unit value is an upwardly biased estimate of the true cost of imported beef.

A comparison of November 1988 U.S. beef prices for chilled and frozen primal cuts and full sets (carcasses) on a CIF Tokyo basis with the corresponding prices of U.S. beef in the Japanese wholesale market is presented in table 4. The calculated tariff equivalent ranges from 63% for frozen tenderloin to 327% for chilled full sets. Note that the tariff equivalents presented in table 4 do not include a profit markup by im-

Brisket	0.99	0.22	358.49	1,125.0	213.10
Full set	1.04	0.22	373.31	1,190.0	218.05

Note: U.S. prices are taken from the USDA *Market News* and the Japanese wholesale prices of U.S. beef are taken from the *Japan Meat Journal*. The exchange rate used is 134.67 yen/U.S. dollar. The insurance and freight cost is based upon a \$484/mt shipping rate. FOB is the cost free on board and CIF is cost, insurance, and freight.

porters or exporters. The tariff equivalents for chilled beef (except striploin) are much higher than are those for frozen beef, which may reflect either Japanese preference for chilled rather than frozen beef or institutional barriers. Because most of the beef imported by Japan is frozen, the tariff equivalent used in the projections is based on the difference between the frozen full sets price and an assumed 10% profit margin for importers. The resulting tariff equivalent is approximately 190% in 1988 compared to slightly less than 100% when the average import unit value for beef is used to calculate the tariff equivalent.

The potential effects of the alternative measures of the tariff equivalent upon projected BMAA beef import levels are illustrated in figure 7. Using a U.S. price plus transportation costs measure (High T) results in substantially higher levels of beef imports compared to the results of using the average import unit value (Low T). The 400,000 metric tons divergence in the results by 1997 is attributable entirely to the difference in the assumptions about border price levels and demonstrates the importance of accurately measuring the tariff equivalent of the quota.

With regard to total consumer meat expenditures, this study assumes that the annual rate of growth in those expenditures over the forecast period is equal to the 2.5% average annual rate of growth for 1981 through 1987. A higher or lower assumed growth rate would likely have

a significant affect on the forecast growth rate of Japanese beef consumption and, therefore, on beef imports.

Figure 8 illustrates the impact of the BMAA upon beef imports, given a low growth rate (1% and a high growth rate (4%) of meat expenditures, compared to the assumed 2.5% growth rate. The projected level of beef imports in 1999 under these three growth rate assumptions range widely from 1.6 million metric tons under the high growth rate assumption to 1.2 million metric tons under the 2.5% growth rate assumption and 0.9 million metric tons under the low growth rate assumption.

Summary and Conclusions

This paper utilizes dynamic simulation analysis to consider the likely consequences of alternative Japanese beef import policies on the Japanese livestock industry and beef imports. The policies analyzed are the recently signed BMAA complete liberalization, and a continuation of the previous policy of small annual increases in the import quota. Measuring the changes resulting from these policy alternatives created modeling difficulties, which included the incorporation of a meat expenditure system into a more complete dynamic model of livestock supply, a shift from an import quota to a tariff as required under the BMAA in 1991, and the out-of-sample price responsiveness of livestock producers.

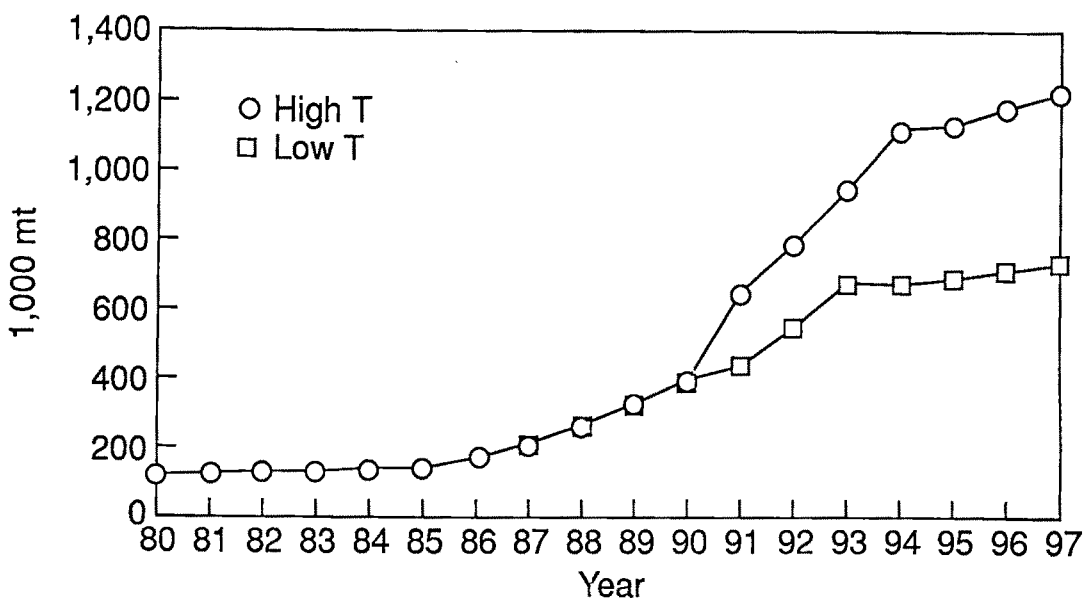

Figure 7. BMAA beef imports under high and low tariff rate assumptions

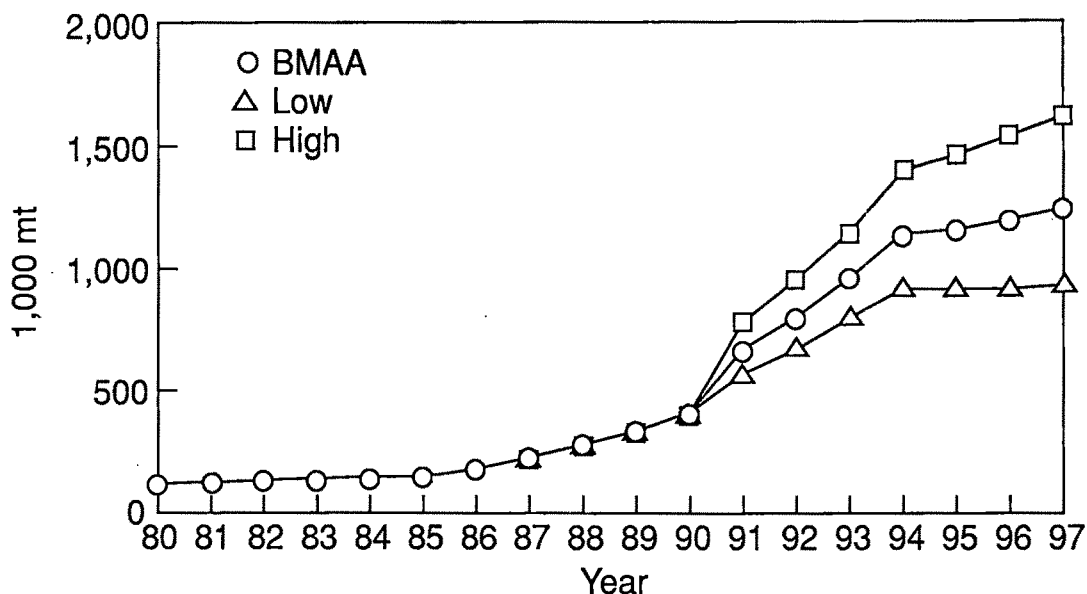

figure 8. BMAA beef imports under alternative total meat expenditure growth rate assumptions

The analytical results lead to a number of conclusions and implications for policy. The projected level of beef imports under complete liberalization suggests that the potential Japanese beef market may be over 1.6 million metric tons by 1991 and over 2 million metric tons by 1997. During the transitional phase of the BMAA, beef imports are likely to increase to the quota level each year. During the post-transitional phase, the additional 25% tariff provision is likely to be invoked. Beef imports are projected to increase by over 67% in 1991 under the BMAA and to reach 1.2 million metric tons by 1997.

The dairy beef industry in Japan will be greatly affected under the policy alternatives. The dairy breeding herd is projected to decrease by about 2% in 1991 under the BMAA and by about 1% under complete liberalization, relative to the results under the quota, because of the substantially lower dairy steer carcass price.

The Wagyu beef industry likely will be affected much less than will the dairy industry under the alternative policies. The Wagyu breeding-herd inventories are projected to decrease within the range of about 11% to 15% in 1991 and from 5% to 8% by 1997, relative to the levels projected under the continuation of the quota, because Wagyu producers are relatively unresponsive to price changes.

The Japanese hog and chicken industries will likely be little affected by the implementation of

alternative policies. The hog industry will be unaffected because the current variable levy is assumed to remain in place. The chicken industry is relatively unaffected because of the low cross-price elasticities with the other meats.

The results of the study are sensitive to assumptions about the tariff equivalent and the growth rates of total meat expenditures used. Consequently, the direction of the change and the comparisons in the movements in the variables under the alternative scenarios in this study, are likely more useful and accurate than are the absolute magnitudes of the simulated values of those variables. Also, many of the modeling techniques developed here may be useful for the other studies of this type that will be necessary during the ongoing GATT negotiations.

The Competitive Structure of U.S. Agricultural Exports

Daniel H. Pick and Timothy A. Park

The competitive structure of U.S. agricultural exports is examined using a model of exporter behavior based on pricing decisions across destination markets. Market power is revealed in the adjustment patterns of export prices in response to exchange rate movements. The results reject the hypothesis that the export pricing decisions by U.S. firms are consistent with price discrimination across destination markets for cotton, corn, and soybeans. The strongest evidence against the competitive market structure is obtained for international trade in wheat, where results indicate that the two largest importers (Soviet Union and PRC) may exert market power to obtain lower prices.

Key words: agricultural exports, exchange rate, imperfect competition, monopoly, monopsonist, price discrimination.

Recognizing the link between imperfect competition and international trade policy, a diverse set of models of imperfect competition have been developed to explain price formation in international agricultural trade (McCalla, Sarris and Teeb-Tsai, Paarlberg and Abbott, Kolstad and Morris). This paper is motivated by Krugman's observation that tests for imperfect competition in international trade can be based on the observed pricing decisions of exporters. Exporters may exercise market power by adjusting prices to different export destinations, resulting in a form of price discrimination. This pricing-to-market (PTM) behavior pertains to decisions by exporters to maintain or even increase export prices when facing currency depreciation relative to the importer's currency.

The PTM phenomenon has been largely neglected in agricultural trade analysis. Given the dominant U.S. trade shares of many agricultural commodities, pricing decisions by U.S. exporters should be examined for behavior consistent with PTM. For example, the U.S. has been a major exporter of wheat, corn, soybeans, and cotton throughout the 1980s and, until the late 1970s, soybean meal and soybean oil.

In this paper, a model of PTM is applied to U.S. exports of wheat, corn, cotton, soybean, and soybean meal and oil. The main objective

is to develop testable hypotheses about the existence of market power in international commodity trade using the PTM framework. A model of imperfect competition is presented based on pricing decisions by exporting firms across destinations. The model is modified to account for price discrimination by government interventions such as the Export Enhancement Program (EEP).

The first section summarizes previous studies on the competitiveness of international agricultural markets. The second section outlines the basic model and presents an empirical specification designed to test exporter behavior. Sections three and four discuss the data sources, results, estimation, and a model extension. The model extension accounts for the possibility that importers exercise monopsony power in the wheat market. Conclusions and directions for future research then are presented.

Imperfect Competition in Agricultural Markets

The literature review first considers the main approaches to modeling imperfect competition in agricultural commodity trade, mainly in wheat, and then considers models based on industrial organization approaches to imperfect competition in international trade. Imperfectly competitive pricing behavior in the international wheat market was mentioned by Mendelsohn and Farnsworth in the 1950s, but McCalla first in-

Daniel H. Pick is an agricultural economist, Developing Economics Branch, ATAD, Economic Research Service, U.S. Department of Agriculture; Timothy A. Park is an assistant professor, Department of Agricultural Economics, University of Nebraska.

roduced a duopoly model of the international wheat market. His model included Canada and the United States, with Canada as the price leader. Alaouze, Watson, and Sturgess developed a triopoly model which incorporated Australia as a major exporter. Carter and Schmitz proposed a model in which wheat importers exercised monopsony power and imposed import tariffs on wheat to maximize welfare gains. An informal test of the model was based on a comparison of actual prices with empirical estimates derived from the optimal tariff solution.

Oligopoly theory spurred the development of other models investigating imperfect competition in agricultural trade. Sarris and Freebairn modeled international prices as the outcome of a Cournot equilibrium in which pricing policies for individual countries were determined by maximizing domestic welfare. Simulations of the world wheat market were performed to examine the effects of various trade liberalization scenarios. Karp and McCalla applied a Nash cooperative dynamic game to the international corn market and developed multiperiod reaction functions for both importers and exporters. Kolstad and Burris developed a spatial equilibrium model in which countries acted as Nash quantity competitors in the international wheat market. Actual trade flows and predicted trade flows from the model were compared to validate the model.

Paarlberg and Abbott combined a model of oligopoly in international markets with domestic interest group influence to endogenize domestic agricultural policy formation. Model validation was based on comparisons of actual and predicted trade and price levels for wheat.

Two key points should be emphasized. First, price discrimination based on pricing to market and incomplete pass-through of exchange rate movements to export prices has not been addressed for trade in agricultural commodities. Second, the models reviewed here reflect a diverse set of behavioral assumptions, sets of agents and countries, and modeling and validation techniques for imperfect competition in international agricultural trade. The models provide indirect evidence for the validity of their underlying behavioral assumptions using simulation analysis and comparisons of observed and predicted market conditions. Statistical tests for market power which distinguish directly between perfect competition and imperfectly competitive pricing decisions have not been presented.

This paper develops a modeling approach based on firm pricing decisions which yields simple

statistical tests of market power, encompassing perfect competition and two models of imperfect competition. The technique can account for specific market characteristics of a commodity. It is proposed as a prelude to the development of full-scale models of imperfect competition. A prime motivation for this study is to apply the theoretical developments and empirical tests developed in industrial organization to trade in agricultural commodities (Dornbusch, Knetter, Feinberg).

Price Discrimination in International Trade

The scenario developed to identify the competitive structure of a market is based on the incomplete pass-through of changes in the exchange rate to import prices. Krugman discussed the possibility that incomplete pass-through will result from price discrimination by exporters toward importing countries. When export prices of foreign firms are maintained or even increased as the currency of the importing country appreciates, PTM has occurred.

Knetter proposed a model which distinguishes between a competitive market and two models of imperfectly competitive behavior. The exporter is assumed to export to N different markets with individual import demand in each market, $i = 1, \dots, N$, represented as

$$(1) \quad q_{it} = f_i(s_{it}p_{it})v_{it},$$

where q_{it} is the quantity demanded by market i in period t , p_{it} is the export price to market i in the exporter's currency in period t , s_{it} is the i th importer's currency per exporter's currency exchange rate in period t , and v_{it} is a demand shifter. The cost structure for the exporter is a function of the total quantity exported and a cost function shifter δ_t :

$$(2) \quad C_t = C(\sum q_{it})\delta_t.$$

Given (1) and (2), the profit-maximization problem is

$$(3) \quad \text{Max } \pi = \sum_{i=1}^N (p_{it}q_{it}) - C_t.$$

The first-order condition is derived by differentiating (3) with respect to the choice variable p_{it} , and expressed in terms of elasticities:

$$(4) \quad p_{it} = c_t [\epsilon_{it}/(\epsilon_{it} - 1)], \\ i = 1, \dots, N, t = 1, \dots, T;$$

where c_t is the exporter's marginal cost in period t , and ϵ_{it} is the demand elasticity for imports in each of the importing countries in period t .

Expression (4) represents the familiar optimal profit-maximization conditions for the price-discriminating monopolist, equating marginal cost to marginal revenue in each market. When the exporter behaves as a perfect competitor, demand elasticities are infinite and do not vary across destinations. Price then equals marginal cost ($p_{it} = c_t$), and prices are equal across all destinations.

In order to test for alternative market structures, Knetter proposed the following cross-sectional-time-series equation:

$$(5) \quad \ln p_{it} = \theta_t + \lambda_i + \beta_i \ln s_{it} + u_{it},$$

where θ_t is the time effect, λ_i is the country effect, and u_{it} is the error term. Equation (5) can be used to distinguish between three models of market structure. In the competitive market structure, export prices will be the same for all destinations; because there is no country effect, $\lambda = 0$. Changes in the bilateral exchange rates will not affect bilateral export prices, implying $\beta = 0$. The time effects represented by θ_t will measure the common price for all destinations.

The second and third structural models involve imperfect competition with price discrimination across destination markets. The second model assumes constant elasticity of demand with respect to the domestic currency price in each of the importing countries, a reasonable approximation for slight movements along the demand curve. In such a model, the markup over marginal cost as given in (4) is constant but may vary over time and across destinations, implying $\lambda \neq 0$. Shifts in bilateral exchange rates do not influence export prices to various destinations, implying $\beta = 0$.

The third model is based on price discrimination with varying elasticities of demand. Under this scenario, the demand elasticities may vary with changes in the exchange rate. Consider a depreciation of the domestic (importer) currency relative to the foreign (exporter) currency. The price faced by domestic consumers then increases. If the demand elasticities remain constant, then the second case results in which exporters are faced with a constant elasticity demand schedule. However, if demand elasticities change, then the optimal markup over marginal cost will change and export price will thus depend on exchange rates. Krugman referred to this scenario as pricing to market because the

optimal markup by a price-discriminating monopolist will vary across destinations and with changes in bilateral exchange rates. In terms of (5), this model implies that $\lambda \neq 0$ and $\beta \neq 0$.

U.S. Agricultural Exports

The model in equation (5) is applied to five major commodities to test for noncompetitive market structure in United States agricultural exports. The five commodity groups and their respective commodity codes (SITC) included corn (0440045); wheat not donated (0410040); cotton (2631040); soybeans (2222040); and soybean oil, cake, and meal (0810024). Data were compiled on a quarterly basis for the 1978–88 period. Quantity and value data were available from the U.S. Department of Commerce Schedule E. The value data are FAS (free alongside ship), which exclude the cost of loading or any other charges or transportation costs beyond the port of exportation. The quantity and value data were used to generate the price (unit value) variable. Exchange rate data were available from the *International Financial Statistics* published by the International Monetary Fund, while the real exchange rates were calculated using the respective CPI as deflator. Official exchange rates for the Soviet Union, the People's Republic of China (PRC), and Thailand were used in the study.¹

For each commodity a pooled cross-sectional-time-series model was specified with $T \times N$ observations for each model. There are $T - 1$ time dummy effects (θ_t) and $N - 1$ country dummy effects (λ_i). Only the major importers were considered in the analysis.

Tables 1 through 5 summarize the results for each commodity, using both nominal and real exchange rate measures. A significant relationship between export prices in any export destination and the bilateral exchange rate implies a rejection of the constant elasticity model. The number of nonzero coefficients, or violations of the constant elasticity model, was approximately the same for each regression using either nominal exchange rates or real exchange rates.

¹ Although these exchange rates are not determined in the free market, they are adjusted by the respective governments to reflect economic conditions. For the Soviet Union, it is often argued that the price of gold or the trade balance should be used as a proxy to the exchange rate. However, the exchange rate for the Soviet Union is monitored and changed on a monthly basis and is a reasonable proxy for an exchange rate which reflects economic conditions in the Soviet Union. Both exchange rate coefficients for the Soviet Union and the People's Republic of China in the wheat equation were not significant.

Positive and significant coefficients on the exchange rate variable occurred four times for both specifications of the exchange rate variable. A negative coefficient is consistent with a model of price discrimination in which exporting firms adjust prices in export markets to offset local exchange rate movements. Positive coefficients imply that exporters in the United States adjust prices upward as the local currency appreciates, exacerbating the impact of exchange rate movements.

Results for the cotton market in table 1 do not support price discriminating behavior across destination markets. Using the nominal exchange rate measure, only the exchange rate coefficient for Portugal differed significantly from zero at the 10% level. The remaining country effects were not statistically significant. Using the real exchange rate measures produced three significant country effects (Canada, Italy, and South Korea) and no significant exchange rate coefficients. F -tests for $\forall \lambda_i = 0$ and $\forall \beta_i = 0$ were not significant.

Knetter noted that the influence of any particular foreign supplier on prices in a specific

market will be reduced as the number of foreign suppliers to a particular country increases. These results, which indicate the absence of market power, are consistent with the structure of the international cotton market in which a relatively large number of exporters makes it difficult for the United States to exercise market power.

Table 2 summarizes the results of the corn market. The results do not support the hypothesis that the United States as the largest exporter of corn engages in price-discriminating behavior in the international corn market. A possible explanation for the results is that corn is usually exported as feed grain; therefore, the importers face various substitution possibilities among feed grains. Only Mexico, in the nominal exchange rate regression, yielded significant country and exchange rate coefficients. Mexico imports corn for tortilla production and, therefore, corn is imported as food rather than feed grain. The relevant F -tests were not significant.

These results are consistent with Karp and McCalla's model of the international corn market using a noncooperative difference game. The results from the difference game suggested that

Note: Values in parentheses are *t*-values. Asterisks denote *t*-values significant at the 10% level. F_{ER} is the *F*-value for testing whether $\forall \beta_i = 0$. F_{CN} is the *F*-value for testing whether $\forall \lambda_i = 0$.

U.S. producers gain most when the U.S. behaves competitively even though the United States is in the strongest position to disrupt world trade. By contrast, an oligopoly model developed by Mitchell and Duncan provided weak support for U.S. price leadership in the coarse grain market during the period 1965–81.

The soybean market results are summarized in table 3. The United States is the major exporter of soybeans, accounting for about 70% of global soybean trade. Increased production and exports from Argentina, Brazil, and Paraguay have diminished only slightly the U.S. share. Brazil's trade policy is designed to insure an adequate supply of soybeans for the domestic crushing industry. Trade restrictions and value-added taxes have discouraged the export of soybeans, while tax credits have been used to promote the exports of soybean oil and meal.

The characteristics of international trade in soybeans and processed soybeans suggest that an imperfectly competitive market structure could result. However, the results do not support this hypothesis, mainly because of the use of various substitutes and other exporters for oilseed products. Only in the case of Netherlands, behind Japan as the second largest importer of soybeans from the United States, did the results yield sig-

nificant coefficients for the exchange rate variable (both nominal and real) and the country effect. These significant coefficients for Netherlands may reflect the importance of the crushing industry in the Netherlands. Both *F*-tests were not significant.

The soybean oil, cake, and meal results are summarized in table 4. In the soybean meal market, the U.S. share of global exports is slightly more than 20%. Increased competition from Argentina, Brazil, and the European Community (EC), primarily Spain and Portugal, have steadily eroded the U.S. share since the late 1970s. The U.S. share of global soybean oil exports is similar to that for soybean meal. Argentina, Brazil, and the EC are again the main competitors.

The country effect and exchange rate coefficient for Canada and West Germany were significant when using both the nominal and real exchange rate measures. The joint *F*-tests for the country effects and exchange rate coefficients were significantly different from zero when the nominal exchange rates were used in the estimation. In the specification using real exchange rates, only the *F*-test for the exchange rate coefficients was significant.

The evidence in support of price discrimina-

ion for soybean oil, cake, and meal was mixed. The significant coefficients on country effects for Canada and West Germany indicate that the United States may have exercised market power in these countries. The findings should be interpreted with caution, however, because the coefficients for the other four countries were not

significant. The results for the soybean meal market reflect the availability of substitutes that exist in the meal market. The availability of substitutes can restrain countries (or firms) from exercising market power.

The strongest evidence to support price discrimination occurred for the wheat market, pre-

sented in table 5. Since the analysis includes the period in which the EEP was implemented, equation (5) was modified to account for this policy intervention. The EEP program was established in response to export subsidies by the European Economic Community. Under the program, targeted countries are eligible for subsidized wheat exports. Among the targeted countries included in this study are the People's Republic of China, the Soviet Union, Egypt, and the Philippines. A dummy variable was set equal to one for all periods and countries during which the EEP was in effect and zero otherwise.

The results indicate that five of the country effects and three of the exchange rate coefficients were significant in the regression using the nominal exchange rate. All country effects and four of the exchange rate coefficients were significant when real exchange rates were used. The F -tests of $\forall \beta_i = 0$ and $\forall \lambda_i = 0$ were strongly rejected, thus rejecting the hypothesis of perfectly competitive market structure in the wheat market.

In both regressions the coefficients isolating the EEP effect were negative and highly significant. This result indicates that the EEP had a significant negative impact on the unit export value of wheat to the targeted countries. The impact of targeted export subsidies such as the EEP for the world wheat market was examined

in more details by Seitzinger and Paarlberg using a Nash bargaining model linked to a spatial price equilibrium model.

Wheat export behavior by the United States is not consistent with complete pass-through of exchange rates changes to importers. The evidence supports the model of imperfect competition with price discrimination across destination markets. Pick and Skully confirmed that significant premiums and discounts in United States wheat exports to different countries exist, even after accounting for class differences and the Export Enhancement Program. Further empirical work should investigate if significant country effects reflect quality differences among wheat exports.²

Model Extensions

While Knetter's model proposes a distinction between a competitive and imperfectly competitive market structure, large buyers may behave as monopsonists. Carter and Schmitz, and Love and Murniningtyas have suggested such behavior in the international wheat market. An im-

² See Veeman and Wilson for the effects of different quality characteristics on the international wheat prices.

porter's influence on its purchase prices may depend on its relative market share.

To examine the impact of monopsony power in international wheat trade, a term which measures the import share of each country from the United States (r_{it}) was added to equation (5). This variable was added to capture the possibility that large importers are able to capture monopsony rent. Thus, if a country can exercise monopsony power and obtain a lower price, the coefficient on the import share would be negative and significant.

Table 6 presents the estimated share coefficients in the wheat market using both real and nominal exchange rate measures in equation (5). The share coefficients for the People's Republic of China were negative and significant in both regressions. The Soviet Union's share coefficient was negative and significant when using the real exchange rate measure. Because both China and the Soviet Union are the largest importers of wheat, these results suggest some exercise of monopsony power. The estimates for Japan did not yield a significant share coefficient. Thus, the conclusions by Carter and Schmitz, and Love and Murniningtyas, which suggested that Japan exerts monopsony power in the international wheat market, were not supported by this analysis.

Additional support for these findings was provided by Blandford, who estimated market share model for wheat and corn. Based on the results, the importing countries are ranked according to

criteria which reflect favorable conditions for the United States in each of the markets. The wheat export markets of the Soviet Union and the PRC ranked almost last (exceeding only the EEC wheat market) compared to the other markets considered.

Conclusions

The competitive structure of agricultural exports from the United States is examined using a model of exporter behavior based on pricing decisions across destination markets. Market power in international agricultural trade is revealed in the adjustment patterns of export prices in response to currency movements. A pooled cross-section-time-series regression model is specified and econometric tests are presented to distinguish between a competitive market and two models of imperfect competition.

The results reject the hypothesis that the export pricing decisions by U.S. firms are consistent with price discrimination across destination markets for cotton, corn, and soybeans. The results are ambiguous for the soybean oil, cake, and meal markets, indicating potential price discrimination against Canada and West Germany.

The strongest evidence against the competitive market structure is obtained for international trade in wheat. A share variable accounts for the impact of large importers of wheat from the United States. The share coefficients are negative and significant for the PRC and the Soviet Union, the two largest importers. As their import shares from the United States increase, these countries obtain lower prices for their imports.

A reviewer has suggested that price discrimination may occur in the margins between CIF and FOB prices. Large multinational exporting firms dominate the market for chartering and shipping services and may exercise market power by influencing the margins. However, Binkley and Harrer noted that the structure of the shipping industry ensures that freight rates remain flexible and do not deviate significantly from the costs of shipping. This lends support for the model of pricing to market developed here based on prices which are exclusive of loading or transportation costs. However, an important research topic is to formally develop tests for price discrimination based on the margins between CIF and FOB prices.

This research highlights the link between industrial organization models and export-pricing

decisions in international agricultural trade. Future work might examine the relationship between exchange rate adjustments and pricing to market in specific industries, focusing on market concentration within an industry and alternative sources of supply. The extent of pricing to market across different commodities and in different countries should also be investigated.

Are More Exports Always Better? Comparing Cash and In-Kind Export Subsidies

Robert G. Chambers and Philip L. Paarlberg

Cash and in-kind export subsidies are compared. It is found that the ability to enhance real farm income via export subsidies is sensitive both to the form (cash vs. in-kind) and the point of policy intervention. In-kind subsidies of the type granted under the Export Enhancement Program can in fact reduce real-farm income. Export subsidies are examined under three separate scenarios: no target price or nonrecourse loan programs, a target price but no nonrecourse loan program; and a nonrecourse loan program but no target price program. The presence of a nonrecourse loan program dampens the impacts of both cash and in-kind export subsidies.

Key words: agricultural trade, export subsidies, Export Enhancement Program.

Before the introduction of the Export Enhancement Program (EEP), two types of export subsidies had been used by the United States: a direct cash subsidy for wheat exports and an export payment-in-kind (PIK) for feed grains, cotton, rice, and nonfat dry milk. Under the original export PIK program, exporters showing proof of export sales were given certificates redeemable for Commodity Credit Corporation (CCC) commodities to be exported (Cochrane and Ryan). The EEP reintroduced in-kind export subsidies in 1985.

This paper compares the relative effectiveness of cash and PIK export subsidies in increasing agricultural exports, real prices, and real incomes. Because agricultural policy ultimately must be judged by how it affects agriculture's relative position in the economy, the framework is general equilibrium. The model considers the interplay between farmers, international middlemen, nonfarm producers, domestic consumers, and foreign consumers. The analysis shows that the ability to enhance real farm income is sensitive both to the form (cash subsidies versus PIK subsidies) and point of policy intervention

(at the farm or export level). In particular, the results demonstrate that PIK subsidies of the type granted under the EEP can decrease real farm income. From production agriculture's perspective, an export PIK program (even though it raises total agricultural exports) is not a sure path to improving agriculture's position in the general economy. Sometimes less exports are better.

We first introduce the model. The second section reexamines, solely for comparative purposes, the consequences of introducing cash subsidies to commercial exporters. The third section examines in-kind export subsidies given to farmers, and the fourth considers in-kind subsidies to commercial traders. The fifth section reexamines these results when the real target price of the agricultural good is fixed. Next, tied PIK export subsidies are considered. Finally, the effects of contemporaneous existence of price-support operations on the results are discussed.

The Model

Technology and Preferences

There are two countries. In the home country, four goods are produced: a nontraded agricultural intermediate good, a nontraded nonagricultural intermediate good, a traded agricultural good, and a traded nonagricultural good. Intermediate-goods production is governed by the input-nonjoint producible output set:

Robert G. Chambers is a professor of agricultural and resource economics, University of Maryland; Philip L. Paarlberg is an associate professor, Department of Agricultural Economics, Purdue University.

Scientific Article No. A6104, Contribution No. 8269 of the Maryland Agricultural Experiment Station.

The authors would like to thank, without implicating them, Bruce Gardner and Brian Fisher for helpful comments.

$$(1) \quad Y(L, K_1, K_2) = \left\{ (z_1, z_2) : z_i \in Y_i(L_i, K_i) \ (i = 1, 2); \sum_{i=1}^2 L_i \leq L \right\},$$

where $z_i \in \mathbb{R}_+$, $L_i \in \mathbb{R}_+$, $K_i \in \mathbb{R}_+$ ($i = 1, 2$) and $Y_i(K_i, L_i)$ is a scalar-output producible output set satisfying usual properties (Chambers). The index 1 refers to the intermediate agricultural good. L_i and K_i are a mobile factor devoted to the production of good i and the total endowment of a nontraded i th sector-specific factor, respectively. The total endowment of the mobile factor of production, L , is in fixed supply and not traded internationally. The production technology is thus of the Ricardo-Viner type familiar from trade theory (Jones, Dixit and Norman). Moreover, assume that

$$(2) \quad Y_i(tK_i, tL_i) = tY_i(K_i, L_i) \quad t > 0.$$

Production of each intermediate output satisfies constant returns to scale.

A dual representation of the technology is the restricted profit function:

$$(3) \quad \begin{aligned} \pi_i(p_i, w; K_i) &= \max_{L_i, z_i} \{p_i z_i - w L_i : y_i \in Y_i(K_i, L_i)\} \\ &= K_i \pi_i(p_i, w), \end{aligned}$$

where w is the price of the mobile factor of production and p_i ($i = 1, 2$) is the price of the i th intermediate good. The linearity of (3) in K_i follows from constant returns to scale. Expression (3) is the quasi-rent accruing to the i th sector-specific factor and $\pi_i(p_i, w)$ ($i = 1, 2$) is the rental rate of the i th sector-specific factor of production. Each $\pi_i(p_i, w)$ is convex and positively linearly homogenous in its arguments, nondecreasing in p_i , and nonincreasing in w . Moreover, assuming that a unique solution to (3) exists implies by Hotelling's lemma that (3) is differentiable and that

$$(4) \quad L_i(p_i, w, K_i) = -K_i \frac{\partial \pi_i(p_i, w)}{\partial w} \quad i = 1, 2,$$

where $L_i(p_i, w, K_i)$ is the profit-maximizing derived demand for the mobile factor in the i th intermediate industry.

Because $K_i \pi_i(p_i, w)$ is the quasi-rent accruing to the owners of the i th sector-specific input, it is interpreted as the income accruing to the i th sector. Thus, $K_1 \pi_1(p_1, w)$ is farm or agricultural income. (For example, K_1 can be interpreted as

agricultural land.) Using the Ricardo-Viner technology permits identification of how different sectors' real incomes are affected by export policies. Thus, the focus is on the real-income distributional effects of these programs. No welfare analysis based on a community indifference curve is presented for two reasons: (a) because all the policies considered below amount to the domestic country giving away real income [see equations (9)], the competitive assumptions of the model insure that the country must fall to a lower indifference curve as a result of the policy; (b) the aggregation conditions required for the existence of such a community indifference curve [individual expenditure functions must be of the GL form (Muellbauer)] are so restrictive that little realism is gained by their imposition.

Domestic demand for the i th intermediate good is given by the well-behaved demand functions $c_i(p_1, p_2, E)$ ($i = 1, 2$), where E is expenditure on goods 1 and 2. Each c_i is homogenous of degree zero in its arguments and is integrable. Because the first intermediate good is an agricultural good, Engel's law suggests that its income elasticity is small. Coupling this low elasticity with the relatively small percentage of income spent by U.S. consumers on food suggests that little generally is lost by assuming that $\partial c_1 / \partial E = 0$.¹

National income (I) is the sum of payments to the mobile factor of production and quasi-rents to the sector-specific factors of production:

$$(5) \quad I \equiv \sum_{i=1}^2 K_i \pi_i(p_i, w) + wL.$$

The traded goods are processed versions of the intermediate goods that are ready for export. Let y_a and y_b be the quantities of the traded agricultural and nonagricultural commodities, respectively. For simplicity, the process of converting the intermediate agricultural and nonagricultural products into final exports delivered to the foreign country is represented by the constant-returns-to-scale technologies:

$$(6) \quad \begin{aligned} y_a &= \alpha y_1 \\ y_b &= \beta y_2. \end{aligned}$$

This technology is assumed to include transpor-

¹ This assumption is made mainly to sharpen the analysis and reduce notational clutter. All of the results that follow generally are ambiguous if income effects on the agricultural good are allowed. However, so long as these effects are small, which empirical evidence (George and King) suggests is the case, they will be dominated by the more direct price effects discussed below.

tation and marketing services for trade which otherwise leave the commodity unchanged.²

International demands for commodities a and b are given by the foreign excess demand functions:

$$q_i = q_i(p_a^*/p_b^*) \quad (i = a, b).$$

Here p_i^* represents the price of commodity i in the foreign country. It is assumed throughout that $q_i(\cdot)$ is an excess demand function such that $q'_b > 0$ and $q'_a < 0$. (Again, to avoid complicating the model we have presumed foreign income effects are negligible.)

Equilibrium

All markets are perfectly competitive. This assumption may appear strong given the Schmitz et al. allegation that the international grains market is characterized by quasi-monopolistic traders. The assumption is made for three reasons. It allows isolating the effects of export subsidies without confounding them with the effects of monopolistic practices by international middlemen. Thus, if a policy is found to affect farmers adversely, it can be attributed to the policy and not the actions of the middlemen. If farmers cannot gain in the presence of competitive middlemen, they are even less likely to gain with noncompetitive middlemen. Second, Bieri and Schmitz; McCalla; Alaouze, Watson, and Sturgess; and Chambers and Woolverton have already analyzed the implications of various policy alternatives in the presence of international grain cartels and quasi-monopolistic traders. In particular, Chambers and Woolverton have shown that the institution of a grain cartel could hurt farmers. Third, the grain traders maintain that they are low mark-up pricers making their profits on volume and not price manipulation. Caves presents empirical evidence supporting this claim. This characterization fits the technology described by (6) above.

The equilibrium conditions for the model in the absence of government intervention are the following:

(7)

Mobile factor

$$\sum_{i=1}^2 K_i \frac{\partial \pi_i(p_i, w)}{\partial w} = -L$$

Intermediate goods

$$K_1 \frac{\partial \pi_1(p_1, w)}{\partial p_1} = c_1(p_1, p_2, E) + ay_a$$

$$K_2 \frac{\partial \pi_2(p_2, w)}{\partial p_2} = c_2(p_1, p_2, E) + by_b$$

Traded goods

$$y_a = q_a(p_a^*/p_b^*)$$

$$y_b = q_b(p_a^*/p_b^*)$$

International middlemen

$$p_a y_a - p_1 a y_a = 0$$

$$p_b y_b - p_2 b y_b = 0$$

Budget constraint

$$E = I,$$

where $a = 1/\alpha$ and $b = 1/\beta$.

The first equation in (7) is the equilibrium condition for the mobile factor of production in the home country. The second and third equations state that domestic production of the intermediate goods equals demand by domestic consumers for the intermediate goods plus the derived demand by international middlemen for the intermediate goods. The fourth and fifth equations are the market-clearing conditions for the traded goods sectors. The next two equations are the zero-profit conditions required by free entry and exit of middlemen. The last is the domestic consumer budget (balance of trade) constraint.

The equation system in (7) has ten unknowns:

$$(p_1, p_2, p_a, p_b, p_a^*, p_b^*, w, E, y_a, y_b).$$

Absent government intervention, however, competitive behavior insures that $p_i = p_i^*$ ($i = a, b$).³ There are enough equations to solve for all the unknowns.

To develop the relationship between p_a and p_b and p_1 and p_2 , substitute the final-good produc-

² More generally some would argue strongly that fixed costs associated with processing are large, e.g., grain for export. This could be incorporated into the present model by replacing (6) with a quasi-homothetic technology. Expression (6) can also be easily generalized to include competitively provided inputs for a more general production structure without seriously affecting the analysis.

³ The analysis assumes, unlike the 1956 situation but approximately like the 1985 situation, that the domestic and world prices are the same.

tion functions (6) into the middleman's zero-profit conditions. The price of the intermediate goods 1 and 2 equals the price of the corresponding final good times α and β , respectively: middlemen are mark-up pricing. Use the equilibrium conditions in the traded goods market to incorporate the foreign excess demands into the equilibrium conditions for the intermediate goods. Income can be substituted for E in the demand functions by the budget constraint. Thus, the system of equations is reduced to a three-equation system plus the international price linkages:

$$(8) \quad K_1 \frac{\partial \pi_1(\alpha p_a, w)}{\partial w} + K_2 \frac{\partial \pi_2(\beta p_b, w)}{\partial w} = -L$$

$$K_1 \frac{\partial \pi_1(\alpha p_a, w)}{\partial p_1} - c_1(\alpha p_a, \beta p_b, I) - a q_a(p_a^*/p_b^*) = 0$$

$$K_2 \frac{\partial \pi_2(\beta p_b, w)}{\partial p_2} - c_2(\alpha p_a, \beta p_b, I) - b q_b(p_a^*/p_b^*) = 0.$$

The homogeneity properties of demands and supplies imply one price can be selected as the *numéraire*. Let w be the *numéraire* and real-prices $\bar{p}_i = p_i/w$, $\bar{p}_i^* = p_i^*/w$ ($i = a, b$), and $\bar{I} = I/w$. All purchasing power and prices, therefore, are measured in terms of units of L . With little loss of generality, all normalized prices are assumed initially to equal one.

Cash Export Subsidies

Although the general equilibrium effects of export subsidies are well understood, they are briefly reviewed here to permit easy comparison with the PIK subsidy results.

Introducing cash export subsidies for the traded agricultural commodity requires modifying the price-linkage between the domestic and foreign markets. The real per unit subsidy is denoted \bar{s} (we presume that initially $\bar{s} = 0$). The relationship between domestic and international prices is then

$$\bar{p}_a^* = \bar{p}_a - \bar{s}.$$

A cash export subsidy must be financed out of domestic income. Equation (5) is modified to read in normalized terms:

$$(9) \quad \bar{I} = K_1 \pi_1(\alpha \bar{p}_a, 1) + K_2 \pi_2(\beta \bar{p}_b, 1) + L - \bar{s} y_a.$$

The first three terms give the real income earned by factors of production, and the last term is the real export subsidy cost.

The effects of introducing this subsidy are captured by

$$(10) \quad \frac{\partial \bar{p}_a}{\partial \bar{s}} = \frac{1}{\Delta} [K_2 \partial_{wp} \pi_2 \beta (a q_a')] \\ \frac{\partial \bar{p}_b}{\partial \bar{s}} = -\frac{1}{\Delta} [K_1 \partial_{wp} \pi_1 \alpha (a q_a')],$$

where

$$\Delta = K_1 \partial_{wp} \pi_1 \alpha (a q_a' - c_{12} \beta) - K_2 \partial_{wp} \pi_2 \beta (K_1 \partial_{pp} \pi_1 \alpha - c_{11} \alpha - a q_a').$$

Here the notation $\partial_{ij} \pi_k$ means the second partial derivative of π_k with respect to price i and price j .

The profit function $\pi_i(\cdot)$ is convex in p and w . Hence $\partial_{pp} \pi_i$ is nonnegative. The homogeneity and convexity of π_i imply $\partial_{wp} \pi_i < 0$. With only two consumption goods complementarity is excluded. The terms c_{ij} ($j = 1, 2$) are thus the Hicksian-demand slopes (recall $\partial c_i / \partial E = 0$) and hence are of opposite signs with $c_{11} < 0$ and $c_{12} > 0$. Thus, Δ is unambiguously positive.

Inspection of the numerators in (10) now yields unambiguous results: $\partial \bar{p}_a / \partial \bar{s} > 0$ and $\partial \bar{p}_b / \partial \bar{s} < 0$. The real domestic price of the traded agricultural good rises while \bar{p}_b falls. (Qualitative results are summarized in table 1.) Consequently, the price of the agricultural intermediate good rises, and the price of the intermediate nonagricultural good falls.

World market prices react differently than domestic prices. The export subsidy lowers the border price of the agricultural good facing the foreign country. [Note the first expression in (10) is less than one.] The foreign country's border price for the nonagricultural good also falls as \bar{p}_b falls because there is no policy intervention in this market. Consequently, trade expands because the excess demands of the foreign country have negative slopes.

The effect of the cash export subsidy on real sectoral income can now be easily inferred. Because \bar{p}_a and \bar{p}_1 both rise, the properties of π_i imply that real farm income rises with the cash export subsidy. (Recall total real income to the i th specific factor is $K_i \pi_i(\bar{p}_i, 1)$ which is non-decreasing in \bar{p}_i .) On the other hand, because \bar{p}_2 falls real nonagricultural income falls. The real income of the mobile factor, L , falls relative to farm income and rises relative to nonagricultural income. Farmers benefit from a cash export

Table 1. Effects of Alternative Subsidies

	Without Target Price or Loan Rate						With Target Prices					
	\bar{p}_a	\bar{p}_b	\bar{p}_1	\bar{p}_2	$\pi_1(\bar{p}_1, 1)$	Total Real Farm Income	\bar{p}_a	\bar{p}_b	\bar{p}_1	\bar{p}_2	$\pi_1(\bar{p}_1, 1)$	Total Real Farm Income
Cash export subsidy	+	-	+	-	+	+	+	0	+	0	0	0

PIK to farmers	-	+	-	+	-	?						
PIK to middlemen	-	?	?	?	?	?						

subsidy given to the international middleman, while nonfarmers lose.

In-Kind Export Subsidy to Farmers

In modeling in-kind subsidies to farmers, the in-kind subsidy amount is not considered a portion of current supply or demand. It only consists of accumulated government stocks. As was true when the EEP was initiated, these stocks are initially assumed isolated from the market and not price sensitive. Moreover, we assume initially that these stocks do not comprise a portion of current flow income of the government. (Both assumptions are relaxed below.) Thus, the in-kind subsidy yields a rightward shift in intermediate agricultural-commodity supply. The analysis, reminiscent of trade growth models, therefore focuses solely on the consequences of an in-kind export subsidy to which farmers have first title and not a *PIK* program where *PIK* payments compensate producers for retiring acreage.

Denoting the in-kind subsidy as *PIK*, the intermediate agricultural market-clearing condition is respecified

$$(11) \quad PIK + K_1 \frac{\partial \pi_1(\bar{p}_1, 1)}{\partial p} = c_1(\bar{p}_1, \bar{p}_2, \bar{I}) + \alpha y_a.$$

Introducing a *PIK* subsidy is analyzed by differentiating the new equilibrium conditions and evaluating all derivatives at *PIK* = 0 to get

$$(12) \quad \frac{\partial \bar{p}_a}{\partial PIK} = \frac{K_2}{\Delta} \partial_{wp} \pi_2 \beta < 0;$$

$$\frac{\partial \bar{p}_b}{\partial PIK} = \frac{-K_1}{\Delta} \partial_{wp} \pi_1 \alpha > 0.$$

The real price of the traded agricultural commodity falls while the traded nonagricultural commodity real price rises. Contrast this with the cash export subsidy result where \bar{p}_a rises and \bar{p}_b falls. The cash and *PIK* export subsidies have opposite effects. To see why notice that the *PIK*-induced rightward shift in agricultural supply makes the agricultural price fall to soak up the resulting excess supply at original prices. The real nonagricultural price rises to divert demand from the nonagricultural commodity to the agricultural commodity. As a result of these price adjustments, \bar{p}_1 falls while \bar{p}_2 rises. These latter real prices movements imply that the real rental rate on the agricultural-specific factor ($\pi_1(\bar{p}_1, 1)$) falls while $\pi_2(\bar{p}_2, 1)$ rises. Agriculture's share in earned national income falls relative to that of the mobile factor and to the owners of the nonagricultural-specific factor. Again, contrast this with the results for a cash subsidy.

As the real prices of the agricultural traded and intermediate goods fall, so do commercial (nongovernment stock) exports of the traded agricultural commodity. Total agricultural exports rise because of the lower world price of the traded agricultural good relative to the nonagricultural good. Noncommercial (*PIK*) exports actually displace commercial agricultural exports.

Although $\pi_1(\bar{p}_1, 1)$ falls, farmers may not lose because the *PIK* subsidy is made directly to them. Because farmers have title to the *PIK* amount, a necessary condition for their real total income to rise as a result of introducing a *PIK* payment is

$$(13) \quad \frac{\partial(\bar{y}_1)}{\partial PIK} \cdot \frac{PIK}{(\bar{p}_1)} > \frac{-PIK}{y_1}.$$

Expression (13) illustrates that when total demand for the intermediate agricultural commodity is very price inelastic, introducing a *PIK*

subsidy to farmers causes a large fall in \bar{p}_1 . The induced effect on farm income is both large and negative. For farmers to gain from the subsidy, the *PIK* amount must be large relative to farm production. In contrast, when total demand for the intermediate agricultural commodity is very elastic, the *PIK* subsidy acts as a virtual lump-sum transfer to farmers and tends to raise their incomes.

That a *PIK* export subsidy to farmers can make farmers worse off apparently has not been clearly understood. Granting the *PIK* export subsidies to farmers has much the same effect as exogenous growth in a traditional trade model.⁴ There, growth, via an increased endowment or technical change, causes an adverse terms-of-trade shift which counters the gain from the output expansion (Dixit and Norman). If the worsening terms-of-trade effect is large enough to dominate the gain from increased output, national welfare falls—growth is “immiserizing.” Whether growth is immiserizing is governed by the elasticities of the model. Here, however, the *PIK* subsidy always deteriorates the terms of trade which in turn always adversely affects the export sector (agriculture). On balance, this adverse trade effect outweighs the *PIK* giveaway if (13) is not satisfied.

In-Kind Subsidy to Exporters

Now consider what happens when the *PIK* subsidy is paid directly to international middlemen. Three recent analyses consider this type of subsidy. Houck examines a general export bonus scheme where the in-kind payment is tied to commercial exports (also see below). Hillberg, and Seitzinger and Paarlberg model EEP in a bargaining theoretic framework. None of these studies consider the general equilibrium consequences of such *PIK* subsidies.

When the EEP was announced in spring 1985, great care was taken to prevent domestic resale of the *PIK* subsidies. Sales were targeted at specific countries, and in-kind subsidies were granted only to companies which had already made sales agreements with importing nations. The attempt to shield domestic markets from a *PIK* export subsidy was not new. Starting in 1956, a *PIK* payment to subsidize wheat and flour exports had been available to exporters from CCC stocks. Certificates redeemable for CCC stocks were made available to exporters upon proof of ex-

ports from private wheat stocks, but the wheat taken from CCC stocks could only be sold for export (Cochrane and Ryan).

The EEP provisions and the 1956 *PIK* program suggest that whether a *PIK* grant to exporters can be resold domestically has important consequences. But it is easy to show that the fungible nature of internationally traded commodities makes such export provisions irrelevant: the same equilibrium conditions emerge whether exporters can resell the *PIK* grant domestically or not (Chambers and Paarlberg). Here, we only consider a *PIK* grant which must be exported.

Consider a *PIK* export subsidy given to the exporting companies which must be exported. The equilibrium condition for the intermediate agricultural good remains the same, but y_1 must now be interpreted as purchases by the trading firms for “commercial” exports. The equilibrium condition for the traded agricultural good must be modified to reflect the *PIK* subsidy. Total exports now equal “commercial” exports plus *PIK* exports:

$$(14) \quad q_a(p_a^*/p_b^*) = \alpha(PIK + y_1).$$

Because the exporting companies sell the *PIK* but only buy y_1 on the domestic market, their zero profit condition becomes

$$(15) \quad p_a\alpha(PIK + y_1) - p_1y_1 = 0.$$

Solving (14) and (15) recursively gives

$$(16) \quad y_1 = aq_a - PIK,$$

$$(17) \quad p_1 = \frac{\alpha p_a q_a}{q_a - \alpha PIK}.$$

Substituting (16) into the intermediate agricultural good's market clearing condition gives the following equilibrium conditions:

$$(18) \quad K_1 \frac{\partial \pi_1}{\partial p_1} = c_1 + aq_a - PIK,$$

$$\sum_{i=1}^2 K_i \frac{\partial \pi_i}{\partial w} = -L,$$

$$p_1 = \frac{\alpha p_a q_a}{q_a - \alpha PIK}.$$

Normalizing all prices by w and choosing units such that initially $p_a/w = p_b/w = a = 1$ and

⁴ We owe this interpretation to an anonymous reviewer.

$PIK = 0$ gives the following comparative static expression:

$$(19) \quad \begin{bmatrix} 1 & -1 & 0 \\ K_1 \partial_{wp} \pi_1 & 0 & K_2 \partial_{wp} \pi_2 \beta \\ K_1 \partial_{pp} \pi_1 - c_{11} & -q'_a & q'_a - c_{12} \beta \end{bmatrix} \cdot \begin{bmatrix} d(\bar{p}_1) \\ d(\bar{p}_a) \\ d(\bar{p}_b) \end{bmatrix} = \begin{bmatrix} 1 \\ q_a \\ 0 \\ 1 \end{bmatrix} dPIK.$$

The first row of (19) [and the last in (18)] shows that the simple linear link between \bar{p}_1 and \bar{p}_a is now broken. The effect on \bar{p}_1 of a PIK subsidy given to middlemen has two parts:

$$(20) \quad \frac{d(\bar{p}_1)}{dPIK} = \frac{d(\bar{p}_a)}{dPIK} + \frac{1}{q_a}.$$

The first part, through \bar{p}_a , emerged in the previous subsidy cases: the PIK subsidy to farmers and the cash export subsidy. To see the origin of the second term recall the following: an in-kind subsidy to exporters enables them to take a smaller return on each commercial sale than before and still break even. While \bar{p}_a is expected to fall as a result of the subsidy (indeed, this is shown later), the secondary effect can ameliorate, and under suitable conditions even overcome, the first effect.

Solving (19) gives (at $\alpha = 1$):

$$(21) \quad \frac{\partial(\bar{p}_a)}{\partial PIK} = - \frac{1}{q_a} \frac{K_2 \partial_{wp} \pi_2 \beta [(c_{11} - K_1 \partial_{pp} \pi_1) - q_a] + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta)}{K_2 \partial_{wp} \pi_2 \beta [(c_{11} - K_1 \partial_{pp} \pi_1) + q'_a] + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta)},$$

$$(22) \quad \frac{\partial(\bar{p}_b)}{\partial PIK} = \frac{1}{q_a} \frac{K_1 \partial_{wp} \pi_1 [(c_{11} - K_1 \partial_{pp} \pi_1) - q_a] + K_1 \partial_{wp} \pi_1 [K_1 \partial_{pp} \pi_1 - c_{11} - q'_a]}{K_2 \partial_{wp} \pi_2 \beta [(c_{11} - K_1 \partial_{pp} \pi_1) + q'_a] + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta)} \\ = - \frac{1}{q_a} \frac{K_1 \partial_{wp} \pi_1 [q_a + q'_a]}{K_2 \partial_{wp} \pi_2 \beta [(c_{11} - K_1 \partial_{pp} \pi_1) + q'_a] + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta)}.$$

The sign of (21) is always negative. A PIK subsidy to middlemen also has the opposite effect of a cash subsidy on \bar{p}_a . The sign of (22) is positive if the foreign excess demand for the agricultural traded good is inelastic. This is true because the denominator of (22) is positive by earlier arguments, while the numerator's sign depends upon the expression $-[q_a + q'_a]$. Because all prices are normalized to unity initially, this expression is $-q_a[1 + \eta]$, where η is the elasticity of excess demand (q'_a/q_a). If excess

demand is inelastic, (22) is positive (recall $K_1 \partial_{wp} \pi_1$ is negative). (This assumes $q_a > 0$, the home country is a net exporter of a .)

Intuitively, an inelastic agricultural excess demand implies that the PIK -induced supply shift yields little quantity adjustment but relatively large declines in \bar{p}_a . This result translates into reduced foreign expenditure for agricultural products which means greater expenditures on nonagricultural products and higher prices for b . If \bar{p}_b rises, i.e., $-(1 + \eta) < 0$ quasi-rent to the nonagricultural-specific factor rises (p_2/w remains linearly related to p_b/w).

A condition for \bar{p}_1 to rise is

$$\frac{1}{q_a} \left(q_a \frac{d(\bar{p}_a)}{dPIK} + 1 \right) > 0.$$

From above $d(\bar{p}_a) < 0$. A necessary and sufficient condition for (\bar{p}_1) to rise is that the numerator of the right-hand side of (21) be less than the denominator. But the only differences between the terms is the presence of $(-q_a)$ in the numerator and q'_a in the denominator. Hence, (\bar{p}_1) rises only if excess demand for the traded agricultural commodity is elastic. This is similar to Houck's result obtained when p_1 is a blend of the commercial and subsidized prices. If excess demand for the agricultural traded good is inelastic, a PIK subsidy to middlemen causes \bar{p}_1 , and thus, $\pi_1(\bar{p}_1, 1)$ to fall. Real farm income

falls not rises. Farmers are hurt not helped by the PIK subsidy.

These results permit determining the effects of introducing a PIK export subsidy on commercial exports. Commercial exports of the traded agricultural commodity are

$$(23) \quad \text{Commercial exports} = q_a(p_a^*/p_b^*) - PIK.$$

Expression (23) implies the following necessary

and sufficient condition for introducing a *PIK* subsidy to exporters to raise commercial exports:

$$(24) \quad q'_a \left(\frac{d(\bar{p}_a)}{dPIK} - \frac{d(\bar{p}_b)}{dPIK} \right) > 1.$$

Substituting from equations (21) and (22) into (23) yields after a slight rearrangement of terms:

$$(25) \quad \frac{-q'_a \left[K_2 \partial_{wp} \pi_2 \beta (c_{11} - K_1 \partial_{pp} \pi_1 - q_a) + K_1 \partial_{wp} \pi_1 (-c_{12} \beta - q'_a) \right]}{q_a \left[K_2 \partial_{wp} \pi_2 \beta (c_{11} - K_1 \partial_{pp} \pi_1 + q'_a) + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta) \right]} > 1.$$

Because the denominator of (25) is positive, the condition for commercial exports to rise is

$$(26) \quad -(1 + \eta) [K_2 \partial_{wp} \pi_2 \beta (c_{11} - K_1 \partial_{pp} \pi_1) - K_1 \partial_{wp} \pi_1 c_{12}] > 0.$$

The term in square brackets on the left-hand side of (26) is positive. Thus commercial exports fall if excess demand is inelastic, $-(1 + \eta) > 0$.

The assumption of zero trader profit implied by pure competition is important to the results in this section. Suppose, to the contrary, that traders only need a zero profit on their commercial sales and are allowed to retain the value of the *PIK* amount as a lump-sum transfer. In this case, the equilibrium conditions are the same as for an in-kind subsidy to farmers. But now farmers always lose because they see falling prices and incomes and derive no income from the *PIK* amount. This intuition suggests that the less competitive is the international grains market, the more likely it is that a *PIK* subsidy will hurt farmers.

Export Subsidies and a Target Price

The results presented above examine the impact of cash and in-kind export subsidies without considering other policies. But trade policies usually operate in concert with other interventions. In the United States, agricultural producer prices are often guaranteed by setting high target prices which become the effective producer price. In this context, an export subsidy is often the trade manifestation of the domestic intervention. Hillberg, for example, shows that the levels of U.S. domestic policy instruments are critical in empirically evaluating EEP.

To examine the sensitivity of results to domestic policy, the subsidy policies are reanalyzed in the presence of a real target price set

above the market-clearing equilibrium price and maintained by deficiency payments. Price-support operations through a nonrecourse loan program are considered separately below.

In this section the effective producer price for the intermediate agricultural good is the real target price which is policy determined and is unchanged by the subsidy program.⁵ If \bar{p}_1 is above the real target price, the analysis proceeds as be-

fore. Only cases where the target price is effective are of interest. The real target price is assumed fixed. If only the nominal price is fixed (the more usual case), then the real producer price of the intermediate good would be free to vary as in earlier sections.

Domestic real income available for consumption is income less the deficiency payment cost:

$$\bar{I} = \sum_{i=1}^2 K_i \frac{\partial \pi_i(\bar{p}_i, 1)}{\partial w} + L - (\bar{p}_1^s - \bar{p}_1) y_1,$$

where \bar{p}_1^s is the real target price. Differentiating the mobile-factor market equilibrium gives

$$(27) \quad K_1 \partial_{wp} \pi_1 d\bar{p}_1^s + K_2 \partial_{wp} \pi_2 \beta d\bar{p}_b = 0.$$

With the real target price fixed, $d\bar{p}_1^s = 0$, and hence from (27) $d\bar{p}_b = 0$. An export subsidy, therefore, causes no change in domestic relative producer prices. Hence, the export subsidy no longer affects the allocation of L . And, because endowments of K_1 and K_2 are fixed, the export subsidy has no effect on domestic production patterns. This result implies, in turn, that the price of the nonagricultural traded good and its intermediate counterpart cannot change. Therefore, with a fixed real target price, all adjustment comes in terms of the domestic consumption price and the price to foreign buyers of the agricultural intermediate and its traded counterpart.

A cash export subsidy's impact on the tradeable agricultural good's real price to consumers and foreigners is

$$\frac{d\bar{p}_a}{d\bar{s}} = \frac{aq'_a}{c_{11}\alpha + aq'_a}.$$

The denominator is clearly negative because it contains own-price effects from domestic and

⁵ Implicitly we assume all producers are in the program.

excess demand. The numerator is also negative. Thus, \bar{p}_a rises in response to the cash subsidy. As above, however, $d\bar{p}_a/ds < 1$, the domestic price of the agricultural commodity rises by less than the subsidy amount and the price abroad falls.

The rise in \bar{p}_a induces an increase in \bar{p}_1 , which reduces domestic demand for the intermediate agricultural good. Because the producer price is fixed at \bar{p}_1^* , no production change occurs. No matter what happens, producers continue to receive the target price. With static production and falling domestic consumption, exports of the agricultural good must rise. (This also can be seen by noting that \bar{p}_a^* falling causes an expansion of trade.) Producer income and the returns to sector-specific factors are the same as before the subsidy policy. A cash export subsidy in the presence of a fixed real target price only acts to increase agricultural exports, it does not improve agriculture's position in the national economy. Subsidy rents are transferred to foreign consumers.

With an in-kind subsidy to farmers, the associated change in \bar{p}_a is

$$(28) \quad \frac{d\bar{p}_a}{dPIK} = (c_{11}\alpha + aq'_a)^{-1}.$$

Expression (28) shows that \bar{p}_a falls in response to the in-kind subsidy. This price decline is necessary to absorb the additional supply of government stocks placed on the market. Total exports are greater as \bar{p}_a^* is also lower.

The consumer price of the agricultural intermediate good also falls. Domestic use of the intermediate rises. Because production is unchanged with the fixed target price and domestic use is greater, "commercial" exports are lower both as a share of total exports and in absolute volume. As before, commercial exports are displaced by exports from released government stocks.

With \bar{p}_1^* constant, sector-specific factor prices remain unchanged by the policy. However, the income of agricultural producers now clearly rises as their volume marketed expands by the amount PIK , which is sold at price \bar{p}_1 . Agriculture, therefore, gains as a result of the export subsidy.

When the in-kind subsidy is given to the international middleman,

$$\frac{d\bar{p}_a}{dPIK} = \frac{\left(-1 + c_{11}\frac{\alpha}{y_1}\right)}{-(c_{11}\alpha + aq'_a)},$$

which is negative. Because \bar{p}_a falls and there is no price wedge in the world market, \bar{p}_a^* falls and total exports rise. With the real target price constant, producers of the intermediate agricultural commodity experience no changes in this policy environment. Subsidy benefits are transferred to domestic and foreign consumers.

Considering the in-kind subsidy to the middleman without the target price, the change in \bar{p}_1 is ambiguous. This result occurs because of the conflict between the negative terms-of-trade effect and the positive direct effect. A similar situation holds here. The change in \bar{p}_1 faced by domestic consumers is

$$\frac{d\bar{p}_1}{dPIK} = \frac{\alpha \left(1 + q'_a \frac{a}{y_1}\right)}{(c_{11}\alpha + aq'_a)}.$$

If excess demand for the tradeable agricultural good is elastic, total exports increase enough to increase the domestic consumption price of the intermediate good. This occurs because the increase in total trade requires an increase in commercial exports which can only be met through a reduction in domestic use. If the excess demand is not elastic, then the change in the domestic price of the intermediate agricultural good depends on the ratio of total trade to commercial trade— $aq'_a(\cdot)/y_1$. Larger in-kind subsidies will raise this ratio by lowering y_a , and hence, will be more likely to raise \bar{p}_1 .

Tied PIK Export Subsidies

So far, all PIK export subsidies have been lump-sum.⁶ While this specification closely approximates the EEP type of PIK subsidy, other forms of PIK subsidies are possible. This section considers PIK subsidies tied to the level of agricultural exports. Only the case where the PIK subsidy is granted to farmers is analyzed. The reader can easily extend the analysis to the case where the PIK subsidy is granted to exporters using previous developments.

⁶ We would like to thank an anonymous reviewer for suggesting the analysis contained in this section.

Let τ denote percent of total exports comprised by the *PIK* subsidy, i.e.,

$$PIK = \tau q_a.$$

This necessitates the following respecification of (11):

$$(11') \quad K_1 \frac{\partial \pi_1(\bar{p}_1, 1)}{\partial p} = c_1(\bar{p}_1, \bar{p}_2, \bar{I}) + (a - \tau)y_a.$$

Differentiating the new equilibrium conditions and evaluating all derivatives at $\tau = 0$ gives the following effects of introducing a *PIK* subsidy tied to total exports:

$$(29) \quad \begin{aligned} \frac{\partial \bar{p}_a}{\partial \tau} &= \frac{q_a K_2 \partial_{wp} \pi_2 \beta}{\Delta}, \\ \frac{\partial \bar{p}_b}{\partial \tau} &= \frac{-q_a K_1 \partial_{wp} \pi_1 \alpha}{\Delta}. \end{aligned}$$

Comparing (29) with (12) reveals that a tied export *PIK* subsidy granted to farmers has the same qualitative effects as a lump-sum export *PIK* subsidy granted to farmers. (This presumes, of course, that when the *PIK* subsidy is granted the subsidizing country exports the agricultural commodity, i.e., $q_a > 0$.)

A Longer-Run View

Thus far, granting the *PIK* subsidy has had no effect on current national income because a *PIK* subsidy is assumed to enter the national income accounts as either transfers from the government to farmers or to exporters.⁷ The effect on national income is a wash unless the demand functions are specified to take income distributional issues into account. A primary justification for this specification is that the original EEP program used stocks accumulated in historical periods by the government. Current flow income was not affected by those transfers. But this analysis ignores an important point. The EEP has not been a one-time export subsidy pro-

gram. Rather it evolved into an ongoing program extending over at least the life of the Food Security Act of 1985.

If all EEP subsidies were granted from government stocks accumulated before the institution of EEP, the analysis would proceed as before. But current EEP subsidies are drawn from government stocks continuously acquired through the government's price-support (typically non-recourse loan) operations. These price-support operations, in turn, are affected by the *PIK*-subsidy program. As *PIK*-subsidies drive market prices down more stocks are acquired through forfeited loans. This has two effects: the price-support operations mitigate the degree to which agricultural prices fall as a result of the *PIK* subsidy and the government incurs additional budgetary expenses out of current flow income to support market prices.

To assess the longer-run consequences of an export *PIK* subsidy, therefore, the government's price-support operations must be incorporated into the analysis. A nonrecourse loan program is introduced in which the government agrees to purchase all commodities offered at a guaranteed price—the loan rate. The CCC regularly acquires stocks of supported agricultural commodities at prices above the loan rate (even after corrected for interest costs, etc.). Therefore, current government acquisitions of stocks are assumed to be governed by $i(p_1/p_l)$, where p_l is the loan rate. We make the following assumptions:

$$i'(k) < 0, \text{ and}$$

$$\lim_{k \rightarrow 1} i'(k) = -\infty.$$

The first assumption means that government accumulation of inventories through forfeited loans declines as p_1 rises relative to the loan rate. The second assumption means that CCC stands ready to buy all of the commodity offered to it at the loan rate: as the market price approaches the loan rate, government demand for inventories becomes perfectly elastic.⁸

These price-support operations are introduced into preceding analyses. The most obvious change is that expression (5) must be rewritten to rec-

⁷ This analysis was suggested to us by an anonymous reviewer.

⁸ Similar specifications are embedded in the FAPRI and Wheat-sim policy models.

ognize the effect loan defaults have on flow income:

$$(5') \quad I = \sum_{i=1}^2 K_i \pi_i(p_i, w) + wL - p_i i(p_i/p_i).$$

The other change is that the intermediate agricultural good equilibrium must be changed to reflect the new source of government demand for the commodity. Hence, rewrite that condition as

$$K_1 \frac{\partial \pi_1(p_1, w)}{\partial p_1} = c_1(p_1, p_2, E) + i(p_1/p_i) + ay_a.$$

The first step is to analyze how the comparative static effects of a cash export subsidy change as a result of the price-support operations. The necessary calculations give the following results:

$$(10') \quad \frac{\partial \bar{p}_a}{\partial \bar{s}} = \frac{K_2 \partial_{wp} \pi_2 \beta (q'_a a)}{\Delta(p_1/p_i)}, \text{ and}$$

$$\frac{\partial \bar{p}_b}{\partial \bar{s}} = \frac{K_1 \partial_{wp} \pi_1 \alpha (q'_a a)}{\Delta(p_1/p_i)}$$

where

$$\Delta(p_1/p_i) = \Delta + \frac{K_2 \partial_{wp} \pi_2 \beta i'(\bar{p}_1/\bar{p}_i) \cdot \alpha}{\bar{p}_i}.$$

By earlier results, $\Delta(p_1/p_i) > \Delta$. And by the assumptions on $i(p_1/p_i)$, it follows that

$$\lim_{k \rightarrow 1} \Delta(k) = \infty.$$

Therefore, as expected, allowing for price-support intervention dampens the price responsiveness to export subsidies in both markets. In the limit, where the market price is "riding" the loan rate, a cash subsidy has no effect on market prices. Because both \bar{p}_a and \bar{p}_b change less than in the absence of price-support intervention, a cash export subsidy is less effective in raising farm income in the presence of a price-support program than in its absence. In contrast, non-farm prices (and nonfarm income) fall less than in the absence of such programs.

Turning to a *PIK* export subsidy given to farmers,

$$(12') \quad \frac{\partial \bar{s}_a}{\partial FIK} = \frac{K_2 \partial_{wp} \pi_2 \beta}{\Delta(p_1/p_i)},$$

$$\frac{\partial \bar{s}_b}{\partial FIK} = \frac{-K_1 \partial_{wp} \pi_1 \alpha}{\Delta(p_1/p_i)}.$$

Again we conclude that price-support programs dampen the price response to the *PIK* program. Real agricultural prices fall less than they would have in the absence of the price-support program and real nonagricultural prices rise less. As the initial p_1 approaches the loan rate, a *PIK* program given to farmers has no price effect in either agricultural or nonagricultural markets. And, in general, because \bar{p}_1 falls less than in the absence of price support, it is more likely, *ceteris paribus*, that a *PIK* subsidy to farmers raises total farm income when a price-support program exists. The price-support operations dampen the adverse terms of trade effect caused by the *PIK* subsidy.

The effect on total government inventories consists of two parts: the *PIK* giveaway and the reaccumulation of inventories through the price-support mechanism. The expression for the total effect is

$$(30) \quad \frac{i'(\bar{p}_1, \bar{p}_i) \alpha K_2 \partial_{wp} \pi_2 \beta}{\bar{p}_i \Delta(p_1/p_i)} - 1.$$

Using (10') and (12') implies that expression (30) is always nonpositive. A *PIK* export subsidy given to farmers always ends with the government not increasing commodity stocks. The long-run implication is that, *ceteris paribus*, an export *PIK* given to farmers eventually dissipates the government's inventories as less and less beginning inventory is available each period to subsidize exports.

As the initial market price approaches the loan rate, the first term in (30) approaches unity. Therefore, if the market price is "riding the loan rate" when the *FIK* giveaway is instituted, all the *PIK* commodity given away is immediately reabsorbed through the government's price-support operations. In this limiting case, the *PIK* giveaway acts as a pure lump-sum transfer program to farmers. Farmers receive a lump-sum transfer equalling $p_i \cdot PIK$. Under these circumstances the demand faced by farmers is perfectly elastic as the CCC buys everything that is offered at p_i . Thus, expression (13) is satisfied.

Finally, consider how a price-support program changes the results for a *PIK* export subsidy granted to exporting companies. Performing the appropriate comparative-static manipulations gives (at $\alpha = 1$):

$$(21') \quad \frac{\partial \bar{p}_a}{\partial PIK} = - \frac{1}{q_a} \frac{[K_2 \partial_{wp} \pi_2 \beta (c_{11} + i'(\bar{p}_1/\bar{p}_l)/\bar{p}_l - K_1 \partial_{pp} \pi_1 - q_a) + K_1 \partial_{wp} \pi_1 (q'_a - c_{12} \beta)]}{\Delta(p_1/\bar{p}_l)},$$

$$(22') \quad \frac{\partial \bar{p}_b}{\partial PIK} = - \frac{1}{q_a} \frac{K_1 \partial_{wp} \pi_1 (q_a + q'_a)}{\Delta(p_1/\bar{p}_l)}.$$

By (22') the price response in the nonagricultural traded goods market is dampened by the introduction of the price-support operations. However, while the traded agricultural good price still falls as a result of the *PIK* export subsidy, it is ambiguous whether it falls by more or less than in the absence of the price-support program. However, in the limit as p_1 approaches the loan rate, \bar{p}_a falls $(-1/q_a)$ units for every unit of the *PIK* subsidy. But as (20) verifies, this last result implies that \bar{p}_1 does not change and, consequently, neither does farm income in this limiting case. Total farm income remains constant. So, in the case which most closely approximates the 1985 situation (market prices riding the loan rate and *PIK* subsidies given to exporters), farmers realize no gain from the *PIK* subsidy. Instead, the export *PIK* subsidy to exporters ends as a lump-sum transfer to domestic and foreign consumers (absent a competitive grains market, it would be a lump-sum transfer to exporters).

Conclusions

This paper demonstrates the differences between cash and in-kind export subsidies. These results are summarized in table 1. Cash export subsidies expand exports by raising domestic prices and lowering the world price. The price of the agricultural product in the subsidizing country rises, thereby benefiting farm producers at the expense of consumers and taxpayers. An in-kind subsidy given to farmers lowers the price received by farmers but expands total farm exports. The *PIK* commodities displace commercial exports. Although real farm production income is lower after the *PIK*, farmers are not necessarily worse off because the in-kind payment is made directly to them. When international excess demand is elastic, farmers may gain from the introduction of *PIK* payments. An in-

kind export subsidy given to competitive international middlemen lowers the world price and expands trade. The effect of the subsidy on farmers is ambiguous. If the excess demand for the agricultural good is elastic, then agricul-

ture's share of national income rises. For an inelastic excess demand, farm income falls.

Analysis of these three subsidy alternatives in the presence of an effective target price leaves most of the results unchanged. However, with the producer price determined by the target price, producer income is not altered by cash export subsidies and in-kind subsidies to international traders. When the in-kind payment is made directly to farmers, producer income is unambiguously higher with an effective target price.

When a price support program is in effect, the impacts of such subsidies are dampened. Government inventories are reduced by in-kind subsidies over the long run. Further, the analysis shows when the market price approaches the loan rate, the *PIK* subsidy given to farmers becomes a lump-sum subsidy, while the cash and in-kind subsidy to traders leave farm income unaffected. The *PIK* commodities given away are immediately reabsorbed through the government's price support operations.

Testing for Input Substitution in a Regulated Fishery

Diane P. Dupont

Input restrictions are commonly used to prevent rent dissipation in fisheries. This paper examines whether these schemes are successful by calculating the degree of input substitution between restricted and unrestricted inputs. Conventional elasticities of substitution cannot be used when the firm faces controls on the use of some inputs. In this case, the appropriate measure of substitution, the elasticity of intensity, must be used. Data from the British Columbia salmon fishery provide evidence of input substitution possibilities for two vessel types. These results call into question the usefulness of input control schemes.

Key words: fisheries, input substitution, normalized quadratic profit function, partial static equilibrium, regulation.

Fish resources can be a valuable source of revenue to cash-strapped governments if the fisheries are regulated efficiently. In the first-best optimum solution, a sole owner maximizes resource rent. However, without property rights to fish, competition among fishermen can result in a complete dissipation of rent (Warming). To preserve resource rents, regulators often restrict inputs (Christy, Karpoff). Typically, control schemes begin as limited entry programs that restrict only the number of vessels allowed to participate in (or enter) the fishery. Subsequently, restrictions upon input usage per vessel are imposed when regulators find that the first set of restrictions does not work (Pearse, Rettig). The ultimate success of input restrictions appears to rest upon whether fishermen can find substitutes for the restricted inputs.

Past research is divided over the substitution possibilities open to fishermen. Crutchfield argues that fishermen face a sharply increasing

marginal cost of expanding against a tonnage restriction which suggests that the fishing vessel's tonnage is used in fixed proportions with all other inputs, e.g., fuel, labor, gear/equipment.¹ On the other hand, Scott claims that the fishing technology allows much scope for substitution. Until recently, empirical evidence has not been available to decide the issue (Strand, Kirkley, and McConnell; Squires 1987a, b, c). Strand, Kirkley, and McConnell estimate a translog direct production function for the limited entry Atlantic surf clam fishery. They plot isoquants between input pairs to show that inputs are not used in fixed proportions. Squires estimates a translog profit function with three variable inputs (labor, fuel, and capital) for the open access New England otter trawl fishery. The elasticities of substitution he computes indicate considerable substitutability between input pairs. However, the fishing vessels in his work do not face input restrictions.

This paper argues that conventional elasticities of substitution, such as those used by Squires (1987c), cannot be used to evaluate a regulatory program that restricts the use by fishermen of certain inputs. These elasticities are obtained from a model that assumes that all inputs can be chosen freely by the fisherman. As an alternative, this paper proposes the calculation of the elasticity of intensity (Diewert), which describes the relationship between an unrestricted and a re-

All errors and opinions are the author's.

¹ Vessel tonnage is a commonly used measure of vessel size and is frequently chosen as the restricted input.

stricted input, to test for the degree of substitutability in a regulated industry subject to input controls. This elasticity may be defined within the context of the partial static equilibrium model discussed by Brown and Christensen. Under this model, fishing firms maximize restricted profits by choosing output (catch) and variable input quantities subject to the constraint that some inputs are restricted. Using this framework the paper shows that conventional elasticities of substitution are biased relative to elasticities of intensity.

The normalized quadratic restricted profit function (Diewert and Ostensoe) is used to estimate the fish harvest technology and the substitution possibilities for the British Columbia commercial salmon fishery, an important regulated Canadian fishery. The potential usefulness of the elasticity of intensity methodology to fisheries regulators is illustrated with the empirical results.

The next section considers the adoption of input restrictions in a fishery. Section three explains why using conventional elasticities of substitution to evaluate input control programs is inappropriate for a regulated fishery, or any regulated industry. Section four discusses the case study, estimation, and data, while section five reports results. The last section provides conclusions and suggestions to policy makers.

Input Restrictions in a Fishery

The conventional argument in favor of input restrictions is straightforward. If the fishery is open access, fishermen continue to enter the industry until total harvesting costs equal total revenues. Alternatively, if there are limited entry restrictions but no property rights to the fish, existing fishermen upgrade their vessels until the same equality is met. In both instances, fishery rent can be entirely dissipated (Gordon, Clark). The fish input is treated as having a zero price. Instead of charging fishermen for the use of this input, government regulators have chosen to restrict the fisherman's use of purchased inputs. If the fisherman has only one input at his disposal, then restricting the input's use will preserve fishery rent completely.

If inputs are substitutable, it is more difficult to restrict input usage effectively. Given an input restriction on vessel tonnage, a fisherman may reoptimize over the set of inputs under his control. For example, he may visit more and further-away fishing grounds, thereby increasing fuel consumption. Alternatively, he may fish

longer hours and use more labor as well as purchase more gear/equipment. In this way, he tries to increase output and increases his use of substitute inputs for the restricted input. Such direct substitution leads to higher harvest costs. Moreover, increased use of these substitutes leads in turn to increased use of their complements. Therefore, the use of variable inputs that may be direct complements to the restricted input may also increase. These actions, too, lead to higher harvesting costs and resource rent dissipation.

Substitution Possibilities between Unrestricted and Restricted Inputs

A partial static equilibrium model (Brown and Christensen) can be used to describe short-run behavior for firms subject to input restrictions. Assuming that the firm is free to vary the quantity of output, then a restricted profit function can be specified. The firm maximizes restricted profit by choosing the quantity of output supplied, y , and the quantities of variable or unrestricted inputs, $X = (x_1, x_2, \dots, x_n)$. In addition to facing exogenous input and output prices, the firm faces upper bounds on the use of inputs, $Z = (z_1, z_2, \dots, z_m)$.

Equation (1) gives the restricted profit function:

$$(1) \quad \pi^r(p_y, W, Z) = \max_{x,y} \{p_y \cdot y - W^T X; (y, X; Z) \in T\}.$$

The output price is denoted by p_y . The vector, W , represents market prices for the n variable inputs. When the restricted profit function in equation (1) fulfills a set of well-known properties defined in Diewert, it is dual to the underlying production function $F(X; Z)$ and to the production possibilities set, T .

Elasticity measures are obtained from the output supply and input demand equations which, in turn, are derived by differentiating the restricted profit function with respect to prices. Own- and cross-price elasticities of demand indicate the nature of the relationships between variable inputs. To determine whether variable inputs are complements or substitutes, it is sufficient only to know the cross-price elasticities of input demand. Equation (2) defines these elasticities, where x_i is the input demand function for the i th input. The elasticity indicates how the optimal employment of x_i by the firm will change in response to an incremental change in the price of the k th input.

$$(2) \quad \epsilon_{ik} = \frac{\partial x_i(p_y, W; Z)}{\partial W_k} \cdot \frac{w_k}{x_i}, \quad i, k = 1, 2, \dots, n.$$

Inputs are substitutes when ϵ_{ik} is positive and complements when it is negative.

A measure of substitution possibilities between unrestricted and restricted inputs is obtained with elasticities of intensity (Diewert).² Because these elasticities are derived from a restricted profit function, all prices and quantities of the restricted inputs, other than the one being considered, are held constant. Equation (3) defines these elasticities.

$$(3) \quad \xi_{ij} = \frac{\partial x_i(p_y, W; Z)}{\partial z_j} \cdot \frac{z_j}{x_i}, \quad i = 1, 2, \dots, n, \text{ and } j = 1, 2, \dots, m.$$

The Z_j 's are the actual levels of the restricted inputs. A negative elasticity shows a substitute relationship and a positive elasticity, a complementary one. For example, suppose that the value of the elasticity between tonnage and gear is -1.5 . This says that an incremental increase in tonnage, the restricted input, would result in a substantial reduction in the optimal employment of gear, an unrestricted input, by the fishing firm. Hence, the firm regards these two inputs as substitutes.

The relationship between the conventional cross-price elasticity of input demand and the elasticity of intensity can be established in the following way. To obtain the former elasticity, define a full static equilibrium profit function as one in which restricted inputs are treated as variable. Partition the input set into two parts, X and Z , and the input price set into two parts, W and R . The profit function becomes $\pi(p_y, W, R)$. Then, the cross-price elasticity of demand between inputs x_i and z_j (where z_j would be a restricted input in the restricted profit function) is given in equation (4):

$$(4) \quad \frac{\partial^2 \pi(p_y, W, R)}{\partial w_i \partial r_j} \cdot \frac{r_j}{x_i} = \frac{\partial x_i}{\partial r_j} \cdot \frac{r_j}{x_i}.$$

However, the right-hand side of (4) can be rewritten as in equation (5):

$$(5) \quad \frac{\partial x_i}{\partial r_j} \cdot \frac{r_j}{x_i} = \frac{\partial x_i}{\partial z_j} \cdot \frac{\partial z_j}{\partial r_j} \cdot \frac{r_j}{x_i}.$$

Equation (6) is obtained by multiplying both the numerator and denominator of the right-hand side

of equation (5) by z_j/z_j and rearranging the resulting expression,

$$(6) \quad \frac{\partial x_i}{\partial r_j} \cdot \frac{r_j}{x_i} = \left(\frac{\partial x_i}{\partial z_j} \cdot \frac{z_j}{x_i} \right) \left(\frac{\partial z_j}{\partial r_j} \cdot \frac{r_j}{z_j} \right), \text{ or}$$

$$\epsilon_{ij} = \xi_{ij} \cdot \epsilon_{jj}.$$

Equation (6) shows that the conventional cross-price elasticity of input demand between inputs i and j (obtained by assuming full static equilibrium and defining the input z_j as a variable input) is the product of the elasticity of intensity between inputs x_i and z_j and the own-price elasticity of z_j . If the own-price elasticity of demand for z_j is elastic, then the cross-price elasticity of demand will be greater than the corresponding elasticity of intensity.³ The converse is true if the own-price elasticity for z_j is inelastic.

Fishery Background, Characteristics, and Data

The commercial salmon fishery in British Columbia is the province's most lucrative and important fishery with annual revenues of approximately \$212 million in 1987 (and \$160 million in 1982, the year for which data are available to estimate the harvest technology). Salmon account for 40% of quantity and 70% of landed value of all catches (British Columbia Ministry of the Environment 1983, 1988). There are five species of salmon: sockeye, pink, chum, chinook, and coho. Four types of vessels are used, and there is a large degree of uniformity of species composition in the catches of the different vessel types. The vessel types are seine, gillnet, troll, and a combination of the last two called gillnet-troll. Each vessel type exhibits some unique characteristics, but all use some combination of labor, fuel, gear, and capital (vessel) inputs. Seine and gillnet vessels use a variety of nets to entrap the salmon, while troll vessels make use of lines, hooks, and bait to entice the salmon. Gillnet-troll vessels use both nets and troll lines. Seine vessels have the largest tonnage and employ from four to six people. Troll vessels are slightly smaller. Gillnet-troll and gillnet vessels are at the lower end of the spectrum. Each vessel is small enough relative to the total number of vessels—in 1982 this was 4,528—to preclude any one vessel exercising market power.

²Diewert defines the elasticity of intensity between a variable commodity (output or input) and a primary (fixed) input and uses the concept to provide comparative statics results for international trade theorems. The elasticity is reinterpreted here to explain the relationships between unrestricted and restricted inputs.

³This relationship explains why Squires (1987a) finds large elasticity values between capital and labor, e.g., 0.726, and capital and fuel, e.g., 2.125, when he estimates a full static equilibrium profit function. Capital's own-price elasticity is -2.821 . However, because conditions in the fishery that he studies meet the specifications of the full static equilibrium approach, the use of conventional elasticity measures is appropriate.

Since 1969 the salmon fishery has been subject to a limited entry program which sets an upper bound on the number of participating vessels. Since 1971, the regulator (Department of Fisheries and Oceans) has restricted the level of tonnage per vessel as a way of controlling fishing effort per vessel. To make the program effective, the tonnage of a replacement vessel can be no larger than that of the old vessel. Furthermore, pyramiding of vessels (i.e., combining the tonnage of two retiring vessels to apply to a new vessel) has been outlawed since 1980. These restrictions impose an effective upper bound upon the tonnage of a given vessel.

In order to examine the ability of fishermen in the British Columbia commercial salmon fishery to subvert regulations through increased use of unrestricted inputs in place of restricted inputs, this research postulates a restricted profit function for each of the four vessel types. Each vessel owner is assumed to maximize restricted profit over the season by choosing the quantity of catch and the quantities of three variable inputs (fuel, labor, and gear/equipment which includes nets, hooks, lines, etc.). The gear/equipment input is a key unrestricted input to which the firm may turn in response to restrictions upon tonnage (Pearse, Rettig). The constraints upon the fisherman's behavior are the harvest production function, the output price, and prices of variable inputs, and the existing quantities of three restricted inputs. These inputs are vessel tonnage and number of fishing days, both restricted by the regulating agency, and the stock of fish available for the season, restricted by nature.⁴

The research brings together a number of diverse data sets. The first, a cross-sectional random survey of Pacific Coast fishermen for 1982, gives fuel expenditures, vessel characteristics, labor quantities, number of fishing days, and gear/equipment inventory information by vessel.⁵ The second set of data is catch and revenue information collected for the regulator by processing companies. Prices for the five subspecies of salmon are used to calculate a Divisia index for aggregate output price and the asso-

ciated aggregate quantity index for each vessel.⁶ Opportunity cost wages are constructed for labor (Squires 1987b) by using average weekly earnings in an industrial composite category by region, based upon each vessel's homeport region.⁷ Marine fuel prices for eleven centers come from Esso Canada Limited. The gear/equipment input, consisting of nets, lines, etc., is considered to be a malleable capital good whose services are not exhausted in one year. A rental cost of gear is calculated for each component using Schworm's modification of Jorgenson's capital services price formula. Schworm's formula allows for the inclusion of the cost of repairs and maintenance, an important consideration for the fishing firm. Quantity and unit rental price data are used to construct a Divisia gear price index for each vessel.

License records from the Department of Fisheries and Oceans Canada give values for the restricted amount of tonnage per vessel. Data on catch and escapement in each of twenty-nine management areas are used to calculate an index of stock abundance. Because stock abundance varies across fishing grounds, each vessel can encounter a different quantity of fish. Stock encountered is calculated as the relative price-weighted abundance of each of the five salmon species in each fishing area weighted by the number of weeks of fishing in that area.

Restricted Profit Function Specifications and Estimation

The normalized, quadratic restricted profit function (Diewert and Ostensoe), one of a class of flexible functional forms that allows for non-constant elasticities of substitution, represents the objective function for the fishing firm. This function has two features that give it an edge

⁴ The number of days fished is a constrained value since the government uses fishing ground openings and closings for conservation purposes. Each vessel owner would likely fish more days if left on his own. Historical data show that, prior to strict regulations on fishing days, the average number of fishing days was much larger than currently (Pearse).

⁵ Only those vessels that caught salmon or salmon and less than 5% of incidental species such as sturgeon, shrimp, and ling cod have been chosen from the survey. The salmon-fishing fleet comprises the majority of vessels operating in the west coast fisheries. Vessels fishing the two other major species, roe herring and halibut, have not been included because they are regulated in ways that differ from regulation of the salmon fishery.

⁶ Insufficient data prevent the adoption of a multioutput specification defined over the five salmon species unless the inputs are aggregated to form a single index. Given that the issue in the paper is whether fishermen can substitute unrestricted for restricted inputs, it is considered more important to disaggregate inputs than outputs. (This is in contrast to Kirkley and Strand, who concentrate upon the relationships between outputs and aggregate their inputs into a single input index.) Aggregating over outputs allows one to examine the relationships between inputs or whether the harvest technology exhibits jointness in inputs (Squires 1987a). If more data were available, it would be interesting to estimate a model with both disaggregated outputs and inputs.

⁷ A share system whereby crew members receive a share of the value of the catch is used in the fishery, but the system is neither complete nor uniform. The system is used mostly for the seine fleet, and shares vary by species and vessel. The available data are incomplete with respect to the relevant values. As an alternative, the opportunity cost approach (Squires 1987b) is a reasonable substitute. A comparison of the data available on shares received by crew members with the calculated opportunity cost wage reveals that the latter follows very closely the former.

over the translog (Squires 1987a, b, c) and the generalized Leontief (Kirkley and Strand).⁸

First, to estimate the elasticity of intensity, a researcher must have parameter estimates for the cross-restricted input terms appearing in a restricted profit function. If the researcher were to adopt the translog, she would have two options. The first would be to estimate restricted input share equations, along with variable input share equations (McKay, Lawrence, and Vlastuin). However, this option requires that markets for restricted inputs are in equilibrium at current market rental prices. This situation is unlikely in a regulated industry. The second option would be to estimate the restricted profit function along with the variable quantity share equations. However, this option may introduce multicollinearity and degrees-of-freedom problems because all parameters appear in the restricted profit function, whereas each input share equation has less than the complete set of parameters. Depending upon the number of variable inputs/outputs and restricted inputs specified in a model, a restricted profit function can often have more than thirty parameters that need to be estimated.

Alternatively, using the normalized quadratic functional form allows the researcher to retrieve the required parameter estimates by estimating a system of output supply/unrestricted input demand equations. There is no need to assume equilibrium in markets for restricted inputs. Furthermore, because each equation has less than the complete set of parameters, there is less likelihood of data-based multicollinearity problems or matrix-singularity problems leading to nonconvergence of parameter estimates.

The second advantage of the normalized quadratic is that a researcher can impose convexity in prices on parameter estimates of the restricted profit function and continue to identify separate elasticities between individual pairs of inputs. If curvature conditions are satisfied, estimated demand and supply functions will be well-behaved. This property is desirable for simulating rents obtained under alternative regulatory schemes (Dupont). Previous estimates of fish harvesting technology have not met assumed

curvature conditions (Squires 1987a, b, c; Kirkley and Strand).⁹

The normalized quadratic restricted profit function defined over four variable quantities (one output and three variable inputs) and three restricted inputs is given in equation (7).¹⁰

(7)

$$\begin{aligned} \pi'(P, W, Z) = & 1/2 \left(\sum_j \alpha_j z_j \sum_i \sum_k a_{ik} p_i p_k \right) / p_y \\ & + 1/2 \left(\sum_i \beta_i p_i \sum_j \sum_h b_{jh} z_j z_h \right) / z_s \\ & + \sum_i \sum_j c_{ij} p_i z_j + \left(\sum_i \beta_i p_i \sum_j b_{ij} z_j \right) / z_s \\ & + 1/2 \left(\sum_i b_{0i} \beta_i p_i \right) / z_s + \sum_i c_i p_i. \end{aligned}$$

Variable quantity prices are indexed by i, k in the following order: p_y (price of output, i.e., salmon catch) p_l (price of labor), p_f (price of fuel), and p_g (price of gear and equipment). Indexing of fixed quantities, j, h is as follows: z_s (stock of fish), z_t (tonnage), z_d (number of fishing days). Because the function is normalized, *numéraires* of p_y and z_s are chosen. Define the matrix A with elements a_{ik} . Because of the linear relationships between rows and columns in the matrix A caused by linear homogeneity, the first row and column of A , e.g., a_{yk} through a_{yg} ($k = y, l, f, g$) are taken to be vectors of zeroes.

The parameters to estimate are $\alpha_j, a_{ik}, \beta_i, b_{jl}, c_{ij}, b_j, c_i, b_0$. Diewert and Wales note that the α_j ($j = s, t, d$) may be chosen arbitrarily and suggest they be set equal to $1/z'_j$, where z'_j is the fixed factor vector for the first observation. Likewise, the β_i ($i = y, l, f, g$) may be set equal to $1/p'_i$. This convention is adopted here.

The normalized quadratic restricted profit function described in equation (7) satisfies the conditions required for it to represent the underlying production technology. The function is linearly homogenous in prices. Symmetry in cross-price terms is obtained by defining the matrix A to be symmetric. The restricted profit function satisfies convexity in variable quantity

⁸ Because the normalized quadratic is a relatively new flexible functional form, there has not yet been any empirical or theoretical work (like that of Christensen and Caves and Barnett and Lee, who find that translog elasticities tend to be closer to one in absolute value, whereas Leontief elasticities tend to gravitate toward zero) to compare it to the translog or the generalized Leontief. Diewert and Wales, however, compare elasticity values obtained from cost functions represented by a translog, a generalized Leontief, and a new functional form that is similar to the normalized quadratic (the symmetric generalized McFadden). Their findings agree with those of the authors cited above. In addition, they find that elasticities from the symmetric generalized McFadden tend to fall between the values for the two other functional forms.

⁹ Wales suggests that nonconvexity may indicate that the chosen functional form does not provide a good fit for the data over the sample range used. Some reasons for failing to obtain convexity are insufficient price variation in the data, multicollinearity, and aggregation of input or output quantities to obtain indexes.

¹⁰ Lopez shows that the function imposes homothetic output-input separability upon the harvest technology. This means that the marginal rates of substitution between input pairs are independent of the levels of individual outputs. Because a single output framework is necessitated by the data, this restriction is a minor limitation of this function.

prices globally (and locally) whenever the A matrix is positive semidefinite.

Instead of estimating the restricted profit function in (7), it is more convenient to estimate the system of four variable quantity equations given in (8)–(9). These equations, one for each of output and the three variable inputs (fuel, labor, and gear/equipment), are obtained from (7) by using Hotelling's lemma. These equations are formulated in actual quantities, not input or revenue shares; therefore, all four equations must be estimated to obtain the parameters of interest.

$$\begin{aligned}
 (8) \quad \frac{\partial \pi^r}{\partial p_y} &= y^*(p_y, p_l, p_f, p_g; z_s, z_l, z_d) \\
 &= -1/2 \left(\sum_j \alpha_{yz_j} \sum_i \sum_k a_{ik} p_i p_k \right) / p_y^2 \\
 &\quad + 1/2 \left(\beta_y \sum_j \sum_h b_{jh} z_j z_h \right) / z_s + \sum_j c_{yz_j} \\
 &\quad + \beta_y \left(\sum_j b_{z_j} \right) / z_s + (1/2 b_0 \beta_y) / z_s + c_y; \\
 (9) \quad \frac{\partial \pi^r}{\partial p_{xi}} &= -x_i^*(p_y, p_l, p_f, p_g; z_s, z_l, z_d) \\
 &= \left(\sum_j \alpha_{yz_j} \sum_k a_{ik} p_k \right) / p_y \\
 &\quad + 1/2 \left(\beta_i \sum_j \sum_h b_{jh} z_j z_h \right) / z_s \\
 &\quad + \sum_j c_{iz_j} + \beta_i \left(\sum_j b_{z_j} \right) / z_s \\
 &\quad + (1/2 b_0 \beta_i) / z_s + c_i \quad \text{all } i = l, f, g.
 \end{aligned}$$

Cross-equation and symmetry restrictions have already been imposed in equations (8)–(9).¹¹ These restrictions include $a_{ik} = a_{ki}$ in all equations for ik and $b_{jh} = b_{hj}$ in all equations and for each jh .

If convexity is rejected by the data, it can be imposed by a reparameterization of the A matrix (Wiley, Schmidt, and Bramble). This reparameterization uses the product of a matrix D and its transpose to replace the A matrix, i.e., $A = DD^T$. The D matrix is a lower triangular matrix with zeroes in the first column as shown in equation (10). (Recall that the first row and column of the A matrix are zeroes due to the linear relationships between the rows and columns imposed by linear homogeneity.)

$$(10) \quad \begin{bmatrix} a_{yy} & a_{yl} & a_{yf} & a_{yg} \\ a_{yl} & a_{ll} & a_{lf} & a_{lg} \\ a_{yf} & a_{lf} & a_{ff} & a_{fg} \\ a_{yg} & a_{lg} & a_{fg} & a_{gg} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ d_1 & 0 & 0 & 0 \\ d_2 & d_2 & 0 & 0 \\ d_4 & d_5 & d_6 & 0 \end{bmatrix} \begin{bmatrix} 0 & d_1 & d_2 & d_4 \\ 0 & 0 & d_3 & d_5 \\ 0 & 0 & 0 & d_6 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

While it is still possible to obtain separate elasticity estimates for each pair of inputs, the reparameterization requires a nonlinear estimation technique. A new set of equations must be estimated using a nonlinear maximum likelihood procedure because the a_{ik} parameters are replaced by the appropriate combinations of d parameters from the D matrix. The correspondence between the a_{ik} and d parameters is as follows: $a_{ll} = d_1^2$, $a_{lf} = d_1 d_2$, $a_{lg} = d_1 d_4$, $a_{ff} = d_2^2 + d_3^2$, $a_{fg} = d_2 d_5 + d_2 d_4$, and $a_{gg} = d_4^2 + d_5^2 + d_6^2$.

Prior to estimation, additive disturbance terms are appended to each of the four variable quantity equations in (8)–(9). Estimation begins with the linear system of equations (8)–(9). Zellner's iterative technique for seemingly unrelated regressions is used in four separate systems of equations (one for each of four vessel types). [The number of observations is as follows: seine (21), gillnet (80), troll (84), and gillnet-troll (60).] Resulting parameters are checked for acceptance of convexity in prices. Because estimates for one of the vessel types (troll) are consistent with this characteristic, no further estimation of this sample is required. The other three samples (seine, gillnet, and gillnet-troll) do not accept convexity.¹² Therefore, in order to impose convexity, these samples are reestimated using maximum likelihood with a system of four nonlinear equations. Space limitations preclude reporting parameter and elasticity estimates for all four samples. (The author will supply them upon request.) Tables 1 and 2 report parameter estimates, their standard errors, and other summary statistics for two representative samples, the seine and the gillnet-troll. Calculated elasticities of intensity are found to be invariant to the imposition of convexity in prices. This is not surprising since only the cross-price terms are replaced when convexity is imposed.

¹¹ At a 5% level of significance, the seine and gillnet-troll samples did not reject symmetry.

¹² This finding manifests itself in downward-sloping output supply functions. Squires (1987c) finds this is the case, as well. Output aggregation is one possible cause; however, insufficient price variation (often a problem with cross-sectional data) is a more likely one. In order to examine the impact of output aggregation, further estimation is undertaken with two outputs formed by aggregating over fresh and canned salmon species. However, convexity is still rejected by the same samples as previously. Squires (1987c) obtains the same result for an even finer disaggregation of outputs.

Results

Results for the seine and gillnet-troll fleets are presented because these vessel types represent two extremes in the fishery and, therefore, establish bounds on results for the entire fleet. For the two vessel types, tables 3 and 4 report estimated cross-price elasticities for variable input pairs. These elasticities are calculated using parameter estimates from the nonlinear estimation procedure and mean values from each sample for the regressors. The appendix gives formulas from the normalized quadratic restricted profit function for these elasticities and for the elasticities of intensity.

Elasticities of intensity are used to examine the relationships between unrestricted and restricted inputs. Table 5 presents these elasticities

ties for the seine and gillnet-troll vessels for both inputs restricted by the regulator (tonnage and fishing days). Looking first at seine vessel elasticities associated with tonnage, labor and gear are substitutes for the restricted input, while fuel is a complement. The elasticity values are large (especially relative to the cross-price elasticities) and significant for the fuel and gear inputs. The direct substitution effect discussed above means that rent dissipation occurs as seine vessel-owners substitute toward the use of increased amounts of gear and labor inputs. The indirect effect of the increased use of labor means an increased use of fuel, its complement. Because gear and fuel are substitutes, the net impact depends upon the relative strength of the sets of elasticities. Nonetheless, the results suggest rent dissipation by seine vessels. This finding accords with Pearse's observations and Dupont's estimates; it is of concern because seine vessels, although smallest in absolute numbers

(8% of the fleet), dominate the fishery by percentage of fish landed (38% in 1982).

Results for the gillnet-troll fleet suggest that all three variable inputs are complements for tonnage (table 5). Furthermore, the elasticity values are large, ranging from 0.452 (labor) to 1.608 (gear), and significantly different from zero in two out of three cases. Thus, there is no direct substitution effect. Moreover, although the cross-price elasticities show that labor and gear are complementary inputs, the values are extremely small and not significantly different from zero. The results support the hypothesis that the gillnet-troll vessel does not have many ways of dissipating fishery resource rent in the face of an input restriction upon a vessel's use of tonnage.

The conclusions are reversed when the elasticities of intensity associated with restricted fishing days are examined (table 5). (Recall that each elasticity is a partial elasticity obtained by holding constant the quantities of other restricted inputs.) With one exception, each variable input has a complementary relationship with fishing days in the samples. The values are inelastic but generally significantly different from zero. Hence, the fishing days restriction is effective in preventing input substitution that can lead to rent dissipation. The one exception is the ability of vessel-owners in the gillnet-troll sample to substitute more gear against a fishing days restriction. They do this by purchasing both gillnet and troll gear/equipment. Then, when a fishing ground is closed to one type of gear, the gillnet-troll vessel-owner switches to the alternative unrestricted type of gear.

Elasticities, not reported in this paper, for the other two vessel types show that the troll vessel is strikingly similar to the seine vessel in its ability to exploit substitution possibilities, while gillnet-troll results represent the gillnet vessel well (with respect to tonnage elasticities). Thus, the British Columbia limited entry program with tonnage restrictions per vessel appears to have been moderately successful in preventing only two of the four vessel types from dissipating resource rent in the salmon industry. The inability of fishermen to find substitutes for the restricted fishing days input has undoubtedly contributed to the regulator's limited success.

Conclusions

Fisheries regulators have now had two decades of experience with quantitative input restrictions

imposed to preserve resource rent. This paper examines whether input control programs can be successful by asking whether the fishing harvest technology allows fishermen to subvert the intentions of the programs by substituting unrestricted for restricted inputs. The paper confirms for the British Columbia commercial salmon fishery, an important regulated Canadian fishery, that these programs have not been effective, as many have argued (Pearse, Rettig). Examination of the elasticities of intensity between the restricted input, vessel tonnage, and the unrestricted inputs provides evidence about the ability of two of the four vessel types (seine and troll) in the fishery to substitute unrestricted for restricted inputs. In so doing, the owners of seine and troll vessels are able to dissipate fishery rent (Dupont). Restrictions on fishing days, on the other hand, do not permit much substitution and are better choices for regulated inputs.

In light of these findings, it is appropriate to argue that the regulators should consider phasing out tonnage control schemes, increasing the use of fishing days restrictions, or replacing input controls entirely with individual transferable vessel quotas or royalty taxes. Difficulties with the imposition of a royalty tax include the determination of the correct rate, the necessity of an annually fluctuating rate in response to stock variability, disincentive effects that encourage illegal landings, and possible distributional effects of tax incidence. Furthermore, taxes are not popular with fishermen. On the other hand, the individual transferable vessel quota (ITVQ) is generating a great deal of interest among fisheries economists (Christy, Scott). One problem with adopting an ITVQ is that it is tantamount to the creation of property rights. Furthermore, as New Zealand's recent experience shows, the ITVQ can create additional problems for regulators. These problems include the bycatch problem (if the fisherman does not have a quota for a particular species, he is likely to throw any unwanted species caught back overboard where there is only a slim chance of survival), administration of quotas associated with a fluctuating fish stock, and what to do with fishermen who catch more than their quotas (Clark, Major, and Mollett).

Given the problems with the alternative forms of regulation and also given inertia in the fishery, input controls likely will continue to be used. However, the potential resource rent available in fisheries is so great that regulators cannot afford to incur the opportunity cost imposed by inefficient regulation. This paper's approach and

findings will be useful to regulators of other fisheries or industries charged with finding innovative ways of implementing input control programs. The regulator would need only to examine the elasticities of intensity between various pairs of variable and restricted inputs. Those inputs with few substitutes or with positive or zero elasticities of intensity would be good choices for input restriction programs. Alternatively, if the regulator chooses to adopt a set of input restrictions, an examination of pairs of elasticities of intensity would help to determine the best mix of restricted inputs. This represents an improvement over the haphazard or politically motivated choices usually made for controlled inputs.

Appendix

The own- and cross-price elasticities between variable inputs are given below in equation (A1) for the normalized quadratic restricted profit function.

$$(A1) \quad \epsilon_{ii} = \left(a_{ii} \sum_j \alpha_j \frac{z_j}{p_j} \right) \cdot \frac{p_i}{x_i} \quad \text{for } i = l, f, g.$$

The elasticity of intensity between tonnage and each of the variable inputs is given in equation (A2) for the normalized quadratic restricted profit function.

$$(A2) \quad \xi_{ij} = \left(\alpha_i \sum_k \alpha_k \frac{p_k}{p_y} + \frac{(B_i)}{z_i} (b_{iz_i} + b_{id}z_d + b_i) + c_{ii} \right) \cdot \frac{z_i}{x_i} \quad \text{for } i, k = l, f, g.$$

Efficient Spatial Allocation of Irrigation Water

Ujjayant Chakravorty and James Roumasset

In the presence of conveyance losses, the efficient quantity of water applied falls with distance from the water source, but the amount of water "sent" (including conveyance losses) actually increases with distance from the source, except toward the tail end of the irrigation system. This implies that if marginal cost pricing were implemented, farmers at the middle and lower reaches of the system would have to pay more money for less water received. The model is illustrated and alternative financing schemes compared for an empirically derived demand function for irrigation water.

Key words: benefit taxation, conveyance losses, irrigation, spatial efficiency, water.

Despite massive public investments in irrigation infrastructure, *ex post* evaluations of irrigation projects in developed and developing countries indicate that actual benefits are substantially below projected levels. Considerable evidence suggests that these low benefits are largely the result of poor on-farm water use efficiencies and rent-seeking activities that result from water charges that are low and often unrelated to water use (Chaudhry, Repetto, Bowen and Young). For example, farmers near the system headworks are said to consume a disproportionate share of irrigation water, while tail farmers are left with scanty and unreliable residual supplies (Reidinger, Wade).

Many governments, faced with increasing political pressure to conserve water and reduce fiscal deficits are considering higher water charges to decrease waste and increase cost recovery from project beneficiaries. There is also increased awareness that low water charges and loosely enforced water rationing guidelines lead to environmental damages and excessive mining of groundwater resources. In general, the problems of water allocation and low user charges contribute to derivative problems in achieving efficiency, equity, fiscal stability, and environmental sustainability.

In order to improve irrigation performance and promote sustainable use of agricultural water, an analytical framework for allocating water and levying water charges is needed (Repetto). Although water financing systems vary widely, traditional concepts of irrigation management imply that farmers be charged uniform prices for equal amounts of water delivered (Bishop and Long, Yoo and Busch, Burness and Quirk). Similarly, evaluations of irrigation systems implicitly assume that equal water allocation is desirable and that head versus tail disparities in water allocation are *prima facie* evidence of inefficiency and inequity. As shown below, however, irrigation policies that prescribe equal allocations of water to farmers may be inefficient because conveyance costs of water increase with distance from the source.

In this paper, conditions for efficient spatial allocation of irrigation water are specified that take into account conveyance losses caused by seepage, percolation and evaporation.¹ In the following section, a theoretical model is outlined that derives rules for optimal allocation of water supplied to farmers at various distances from a water source. Optimal water prices are developed at each location, and their implications for rents and equity are examined. The subsequent section illustrates the analytical results for an empirically derived water demand function.

The authors are, respectively, an acting assistant professor of agricultural and resource economics and a professor of economics, University of Hawaii.

The authors are grateful to Ted Bergstrom and Sumner La Croix for helpful discussions and to three anonymous referees of this *Journal* for comments that substantially improved the paper.

¹ Tolley and Hastings incorporate conveyance losses to investigate the gains from reallocation of water from the North Platte River. However, their model does not yield general results. The model proposed here is not only more general but shows the relationship between conveyance efficiency and irrigation system design, user charges, and farmer welfare.

Efficiency Rules: A Framework

Abstracting from the costs of information and enforcement, efficient spatial allocation requires equal marginal value products of water measured at a common source point (O'Mara). The purpose of this section is to derive the equal (gross) marginal product rule and demonstrate its implications for (net) marginal value products and water allocations at the farm level and for determination of optimal system size.

Consider a simplified one-period (one season) model of an irrigation system with water supplied from a point source to a canal. Seasonal variabilities in water supply and storage are not considered. Farmers draw water at various points along the canal located at a variable distance y from the source, $y = 0$ representing the water source, and y increasing away from it. Let $Q(y)$ be the gross volume of source water sent to a farmer located at y , and $q(y)$ be the net water received after conveyance losses.² Then the relationship between source water $Q(y)$ and received water $q(y)$ is given by

$$\begin{aligned} (1) \quad & q(y) = Q(y)h(y) \\ & q(y), Q(y) \geq 0; \\ & 0 \leq h(y) \leq 1; h(0) = 1; \\ & h'(y) < 0; h''(y) \leq 0, \end{aligned}$$

where $h(y)$ denotes conveyance efficiency as a function of distance of farmer from source. Conveyance efficiency decreases with distance at an increasing rate. The major sources of conveyance loss are seepage and percolation. Evaporation losses are considered unavoidable and are ignored because, even if the water is stored and conveyed, it will evaporate, although at a different rate. Investments in canal lining and maintenance reduce $h(y)$.

In this model, we abstract from differential conveyance investments over space and from the choice of conveyance technology.³ Conveyance losses from the farmgate to the root zone of the crop can be regarded as given such that the yield-water relationship is well defined in terms of water delivered at the farmgate. The model also abstracts from the externality effects of convey-

ance losses on downstream water quality or on irrigation return flows.

We assume a one-input, one-output production function for received water that holds for each farmer in the system.⁴ Output per unit area is then given by a production function $f(q)$, which has the usual properties that apply to stage II of the neoclassical production function: $f(\cdot) > 0$; $f'(\cdot) > 0$; $f''(\cdot) < 0$. The value of marginal product function for received water on land of a uniform quality can be written as

$$(2) \quad VMP_r = Pf'(q),$$

where P is the competitive crop price. From (2), $\partial VMP_r / \partial q < 0$, a result that follows from the concavity of the production function.

The value of marginal product for received water at the source (VMP_s) can be defined (by assuming the necessary continuity and differentiability properties and using the chain rule) as

$$(3) \quad VMP_s(y) = Pf'(Q) = Pf'(q)h'(y) = VMP_r h'(y)$$

from (1) and (2), and

$$(4) \quad \partial VMP_s / \partial y = Pf'(q)h''(y) < 0,$$

using (1). Condition (3) gives the relationship between the two functions VMP_r and VMP_s , one as a function of water measured at the farm and another as a function of water measured at the source. From (4), the value of marginal product of each unit of source water decreases with distance of the farm from source. Intuitively, as y increases, more source water must be sent to produce one unit of received water on the farm, leading to a lower marginal value product at the source.

VMP_s curves can now be derived as a function of source water for farmers at different locations along the canal. Define q^m and $Q^m(y)$ as the amounts of water at which $VMP_r = 0$ and $VMP_s(y) = 0$, respectively. Note that from (2), q^m is not a function of y . For the farmer at the source ($y = 0$), $q^m = Q^m(0)$, and when $y > 0$, $q^m = Q^m(y)h(y)$, from which we get $Q^m(0) < Q^m(y)$. In other words, the amount of source water at which VMP_s becomes zero increases with distance.

² The theoretical construct used in this paper parallels that presented in Caswell and Zilberman, although the nature of the problem is different.

³ For a model that allows for endogenous choice of conveyance technology and investment in on-farm water conservation, see Chakravorty, Hochman, and Zilberman.

⁴ The monocropping assumption is retained for model simplicity but can be relaxed easily by specifying a unique production function for each farmer. Differences in farmers' preferences, skills, and financial endowments can also be accommodated by indexing on the production function.

The above results can be used to draw $VMP_s(y)$ curves at different distances from the source as shown in figure 1. For the farmer located at the source, $VMP_s(0) = VMP_r$ and $q^m = Q^m$. Curves $VMP_s(y_1)$, and $VMP_s(y_2)$ at increasing distances from the source flatten out toward the x -axis, as shown.

The rule for optimal spatial allocation of water is now derived by maximizing consumers' plus producers' surplus, subject to a capacity constraint as follows:

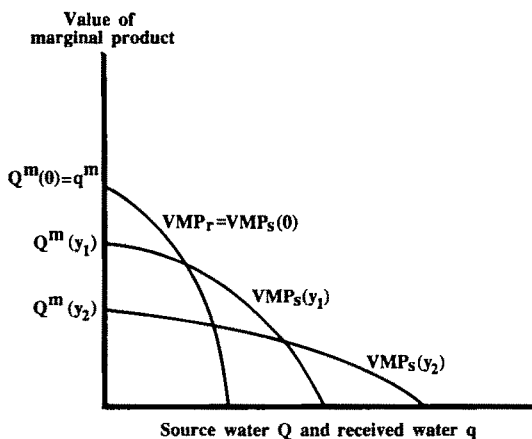

$$(5) \quad \text{Maximize} \quad \sum_{i=1}^n \int_0^{Q^i} VMP_s^i(\beta) d\beta - \int_0^Z C'(\theta) d\theta,$$

subject to

$$Z = \sum_{i=1}^n Q^i,$$

where i represents the i th farmer and $i = 1, 2, \dots, n$; Z is the total stock of water at source; $C'(Z)$ is the total long-run marginal cost of water; and β and θ are variables of integration. In this discrete optimization problem, each farmer i is associated with a distance y . In a continuous model, the same result could be obtained by summing the area under the VMP_s function for each y .

The first term in (5) represents the aggregate willingness-to-pay schedule. It is obtained by the horizontal summation of the VMP_s curves for each

Note: Q and q are related by the equation $q(y) = Q(y)h(y)$.

Figure 1. Position of value of marginal product curves at various distances from the water source where $0 < y_1 < y_2$

of the n farmers in the system. However, all the n farmers need not be within the efficient boundary of the system because the allocation rule derived from the above optimization exercise gives an efficient boundary beyond which farmers will not receive any water allocation. Choosing a value of n large enough will ensure the optimal solution (the allocation to some farmers may be zero).

$C'(Z)$ is the sum of the marginal costs of supply and distribution. The marginal cost of water supply includes the per-period equivalent of capital construction costs and costs of operation and maintenance of the head works. The marginal cost of distribution includes construction, operation, and maintenance of the canal as well as pumping and metering costs. The marginal cost of supply (distribution) usually decreases (increases) with capacity (Koenig). The resulting total marginal cost function could be rising or falling with Z . We have assumed that the topographical constraints on system expansion are not binding such that economies of scale in the total marginal cost schedule have been fully exploited, giving us a rising marginal cost curve. In an *ex ante* setting, the long-run marginal cost of water will be determined endogenously by choosing an optimal water stock, Z . However, if the model is applied to an existing project with a fixed capacity, $C'(Z)$ will be a short-run marginal cost function.

Homogeneity in demand is assumed for the purposes of allocation of capital costs among consumers. The marginal cost-based pricing rules, however, generally will not be optimal if users are heterogenous or if there are decreasing costs or jointness of supply. In those situations, other pricing rules, such as those based on incremental pricing, might be more relevant (Loehman and Whinston).

From (5), the following lagrangian can be maximized:

$$(6) \quad L = \sum_{i=1}^n \int_0^{Q^i} VMP_s^i d\beta - \int_0^Z C'(\theta) d\theta - \lambda \left(Z - \sum_{i=1}^n Q^i \right)$$

with respect to the decision variables Q^i and Z , where λ is the usual Lagrange multiplier. The first-order conditions are as follows:

$$(7a) \quad VMP_s^i = \lambda, \text{ and}$$

$$(7b) \quad C'(Z) = \lambda,$$

giving

$$(7c) \quad VMP_s^i = C'(Z),$$

where λ represents the shadow price of water at the source. Equations (7) equate the shadow price λ to the value of marginal product at source for each farmer and to the long-run marginal cost at optimal system capacity. They give the equilibrium condition for optimal allocation of water under spatial efficiency.

Condition (7b) gives Z^* , the optimal stock of water at source.⁵ Let us denote the optimal values of q and Q (those satisfying condition 7) by q^* and Q^* , respectively. Equation (7a) can be rewritten as $\lambda = Pf'(q^*)h(y)$ and totally differentiated to yield

$$(8) \quad dq^*/dy = -f'(q^*)h'(y)/f''(q^*)h(y) < 0,$$

which implies that farmers further from the source receive less (or net) water. Differentiating (2) and using (8) yields $dVMP_r(q^*)/dy = Pf''(q^*)dq^*/dy > 0$. The above discussion can be summarized as follows:

PROPOSITION 1. *Optimal allocation implies that the value of marginal product of water at the source is equal across farmers. The on-farm value of marginal product of water is unequal across farmers and rises with distance from the source. At the optimum the value of marginal product at source equals the total long-run marginal cost of water.*

⁵ Z^* is optimal given an exogenously fixed conveyance system. If the conveyance was endogenously chosen, the optimal water stock might be different.

Figure 2 shows the determination of the shadow price, λ , at the intersection of the aggregate marginal benefit and marginal cost curves. The aggregation of marginal benefit curves is in units of source water. There is a unique transformation from units of source water to units of water received for each farmer through condition (1). Here, λ is equated to individual VMP_r curves to give the optimal source water allocation $Q^*(0)$ at $y = 0$, and $Q^*(y)$ at any downstream location y . Water received by a farmer at the source $q^*(0)$ is the same as water sent, while an amount $q^*(y) = Q^*(y)h(y)$ is received at any downstream location y after conveyance losses.

Spatial Allocation of Source Water

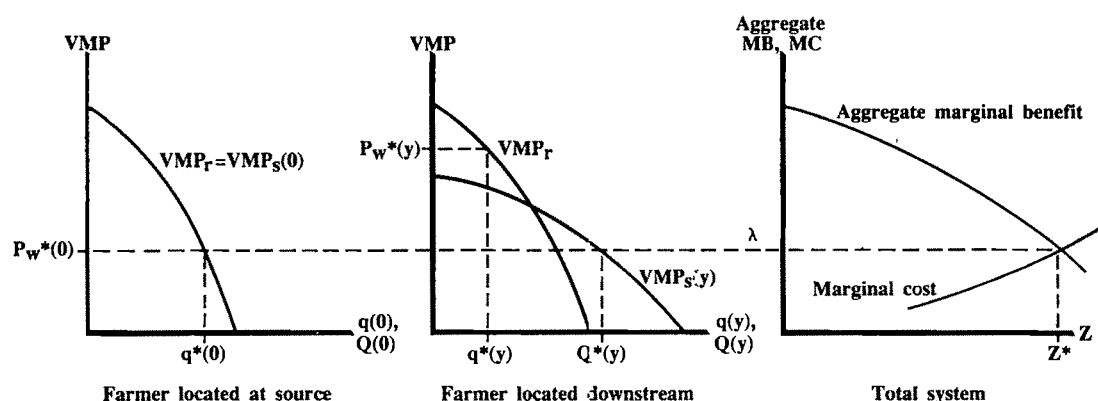

The optimal allocation of source water for each farmer can now be determined by differentiating (1) and substituting (8) to get

$$\begin{aligned} dQ^*/dy &= [-f'(q^*)h'(y)/f''(q^*) - q^*h'(y)]/h^2(y), \\ &= [1/\varepsilon - 1] h'q^*/h^2, \end{aligned}$$

where $\varepsilon = -f''(q^*)q^*/f'(q^*)$ is the absolute value of the elasticity of marginal product of received water in crop production. Hence, $dQ^*/dy = 0$ if either $q^* = 0$ (which is trivial) or $\varepsilon = 1$. Evaluating d^2Q^*/dy^2 at $\varepsilon = 1$ and cancelling terms yields

$$\left. \frac{d^2Q^*}{dy^2} \right|_{\varepsilon=1} = - (d\varepsilon/dy) q^* \cdot h' / h^2 < 0$$

because $d\varepsilon/dy = -f''/f' \cdot dq^*/dy = -f''/$

Note: VMP = value of marginal product, $q(y)$ = water received and $Q(y)$ = source water related by the equation $q(y) = Q(y)h(y)$. MB = marginal benefit, MC = marginal cost, Z = total stock of water, P_w = effective price of water, λ = shadow price of water.

Figure 2. Determination of optimal stock of water, allocation, and pricing

$f' \cdot (-f'h'/f''h) = h'(y)/h(y) < 0$. Therefore, the $Q^*(y)$ function has a local maximum at $\varepsilon = 1$. These results can be combined as follows:

PROPOSITION 2. *Spatial efficiency implies that the allocation of source water increases with distance from source until the absolute value of elasticity of the marginal product for received water equals unity. Optimal water sent decreases with distance beyond that point.*⁶

Note that the length of the canal L (and hence the irrigated area, because we have assumed constant width) is endogenously determined at the point where farmers do not receive any water allocation, or $q^*(L) = 0$.

Spatial Distribution of Charges and Rents

In this section we derive optimal water prices and spot rents accruing to farmers at each location along the canal. The localized shadow price of received water at a distance y is $P_w(y)$. Efficient allocation requires that the marginal product of received water be equated to its shadow price, or $P_w(y) = VMP_r(q^*) = \lambda/h(y)$, using (3) and (7a). At the source, the localized shadow price of water is equal to its system shadow price, since $h(0) = 1$. In addition, $dP_w/dy = -\lambda h'(y)/h^2 > 0$, i.e., the localized shadow price of water increases away from the source.

Marginal cost pricing implies that farmers at any location y pay either the system shadow price of water per unit of source water or the localized shadow price per unit of received water. Both satisfy $\lambda Q^* = (\lambda/h(y))q^* = P_w q^*$ from (1). Intuitively, both marginal cost pricing solutions are equivalent because the total products from source water and received water are equal [from equation (7), marginal cost pricing is the same as marginal product pricing]. It can be shown, by changing the variable of integration, that the areas under the corresponding value of marginal product curves for source water and received water are equal, or

$$(9) \quad \int_0^{q^*} VMP_r d\alpha = \int_0^{Q^*} VMP_s d\tau,$$

where α and τ are variables of integration.

⁶ In the presence of topographical constraints, q^* might lie within the elastic segment of the VMP_r function, in which case $Q^*(y)$ will be a monotonically increasing function of y without an interior maximum.

At marginal cost prices, spot rents from land $R(y)$ at location y are given by

$$(10) \quad R(y) = Pf(q^*) - P_w q^*.$$

Differentiating (10) with respect to y yields

$$R'(y) = dq^*/dy[Pf'(q^*) - P_w] - q^* \cdot dP_w/dy < 0$$

because $Pf'(q^*) = P_w$; or spot rents decrease away from the source when each farmer is making the optimal decision given his (her) location.

In order to examine the effect of conveyance efficiency on optimal water prices and rents, (10) is differentiated with respect to $h(y)$ to obtain $dR/dh = q^* \lambda / h^2 > 0$, which indicates that a higher conveyance efficiency increases land rents. Similarly, $dP_w/dh = -\lambda / h^2 < 0$ and $d^2 P_w / dh^2 = 2\lambda / h^3 > 0$, or increased conveyance efficiency lowers the localized shadow price at an increasing rate. We can thus state the following:

PROPOSITION 3. *Under marginal cost pricing, the localized shadow price of water increases with y and decreases with improved conveyance efficiency. Land rents net of water charges decrease with y and increase with improved conveyance efficiency.*

These results explain the behavior of farmers in response to any given shadow price of source water λ . All farmers pay the same shadow price per unit of source water. As distance from the source increases, the divergence of VMP_r from VMP_s increases, so that the effective price per unit of received water becomes increasingly greater than the price per unit of source water.

The marginal cost pricing solution is shown in figure 2. At the source, the localized shadow price $P_w^*(0) = \lambda$, corresponding to the optimal quantity received $q^*(0)$, is read off the VMP_r curve. For a farmer located at any y , the price for $Q^*(y)$ units of source water is λ . The localized shadow price for $q^*(y)$ units of received water is given by the VMP_r curve, $P_w^*(y)$. Under marginal cost pricing, water charges for the downstream farmer could be expressed as $\lambda Q^*(y)$ or $P_w^*(y)q^*(y)$.

Even though marginal cost pricing is efficient, it may still be objectionable on equity grounds, given that rents near the system head are much higher than those at the tail of the system and because farmers in the middle and tail of the system may pay more money for less total water received.⁷ Moreover, marginal cost pricing

⁷ "Head" and "tail" are relative terms that distinguish the location of the two parties *vis-à-vis* one another.

ing is not necessary on fiscal grounds. Because marginal cost is rising, marginal cost pricing would lead to more than 100% cost recovery. If rationing mechanisms are available to set quantity independently of water charges, then efficient allocation can be achieved without resorting to marginal cost pricing. This facilitates the apparent separability of efficiency and equity and permits a range of possible taxation schemes, including the following:

Rule 1. Proportional benefit taxation. Project beneficiaries could pay in proportion to their individual benefits (Wicksell). This scheme would involve tail farmers receiving less net rents than head farmers, although the benefit distribution would be less skewed than under marginal cost pricing.

Rule 2. Equal rents. The total cost of the system is to be shared among farmer beneficiaries so as to equalize the net rents for all farmers in the system. However, equalizing rents would induce rent-seeking pressures at the boundaries of irrigation systems for system expansion. This is a serious problem of irrigation design in many parts of the world where the target irrigated area is much larger than what the system capacity can efficiently support (Repetto).

Rule 3. Equal charges. Farmers are charged equal amounts for membership in the system. This may provide a pragmatic compromise where the administrative costs and political feasibility of collecting differential water charges is a concern. Equal charges do not achieve equal rents but at least eliminate the "more money for less water" inequity of marginal cost pricing. These alternative financing schemes are illustrated below.

Low versus High Conveyance Losses: An Application

The above model is illustrated by taking conveyance and production functions that closely represent the physical and engineering characteristics of irrigation systems. Representative patterns for the price, quantity, and rent functions are obtained under spatial efficiency for conditions typical to actual irrigation systems.

We construct a *VMP*, function from a survey of functional water-use yield relationships (Hillel) and from linear programming studies of cash crops in Pakistan (Carruthers and Clark). Hillel approximates a yield-water use curve with two segments—a flat portion with constant marginal product and a downward-sloping portion with decreasing marginal product at higher quantities of water:

(11)

$$VMP_r = \begin{cases} 1.75 & \text{for } 0 \leq q \leq 0.3 \\ 2.66 - 3.0 \cdot q & \text{for } 0.3 \leq q \leq 0.875, \end{cases}$$

where *VMP_r* and *q* are in U.S. cents and meters of water, respectively. The two-part function is more accurate than the uniformly downward-sloping curve usually assumed because, at low quantities of water, on-farm losses through deep percolation and evaporation are proportionately higher, justifying a relatively high but constant marginal product over some range of water use. The above function can be treated as a special case of the more general concave, downward-sloping functions analyzed in the previous sections.

The loss of water from seepage and evaporation is assumed proportional to the volume of water carried in the canal (e.g., Tolley and Hastings). Thus, (1) becomes

$$(12) \quad q = Q \cdot e^{-ay},$$

where *a* is the conveyance loss coefficient. Values of *a* from 0.015–0.02 are commonly found in developing country irrigation systems, where canals are often unlined or have linings of low quality, maintenance is poor, and evapotranspiration is high because of higher ambient temperatures (Bos and Nugteren, Hillel). In the simulations that follow, alternative values for *a* of .01 and .02 have been considered.

We assume a hypothetical long-run marginal cost function

$$(13) \quad C'(Z) = Z \cdot 10^{-6}/30,$$

where *C'()* is in cents and *Z* is in cubic meters. Although the marginal cost function for water supply can vary with specific irrigation technologies, projects, and geographical region, a linear form is assumed for simplicity. The total width of the system is 1,000 meters (500 meters on each side of the canal) with a uniform farm size of 5 hectares, which means that canal outlets to successive farms are located every 50 meters.

By taking a starting value of *Z*, we can com-

pute $C'(Z)$ and λ from (13) and (7b). Conditions (7a) and (3) give VMP_s and VMP_r at $y = 0$. From (11), we obtain q^* and Q^* . Because a is known, $h(y)$ is known; and, hence, $P_w(y)$, $q^*(y)$, $Q^*(y)$, and $R(y)$ can be directly obtained. This process is continued for each y until the total stock of water Z is exhausted. By iterating on Z , we choose the optimal Z^* that maximizes total net benefits as defined by the objective function in (5). The efficient length of the canal L is thus determined endogenously.

Simulation Results

Figure 3 and table 1 show the water allocations and charges under alternative conveyance losses and taxation schemes. The results can be summarized as follows:

(a) If conveyance efficiency is low, the aggregate marginal benefit curve shifts up, leading to increased aggregate water use, a higher shadow price of water at source, and a larger irrigated area (see fig. 3, where the efficient length of the system increases from 37.2 kms. to 54.5 kms.).⁸ In this case, reducing the conveyance loss coefficient by one-half leads to expansion of the command area by almost 50%.

(b) Under both high and low conveyance loss regimes, source water allocations increase away from the head and are maximized at about 25 kilometers from the source (see fig. 3). Farmers

⁸ Because width is assumed constant, irrigated area is proportional to canal length.

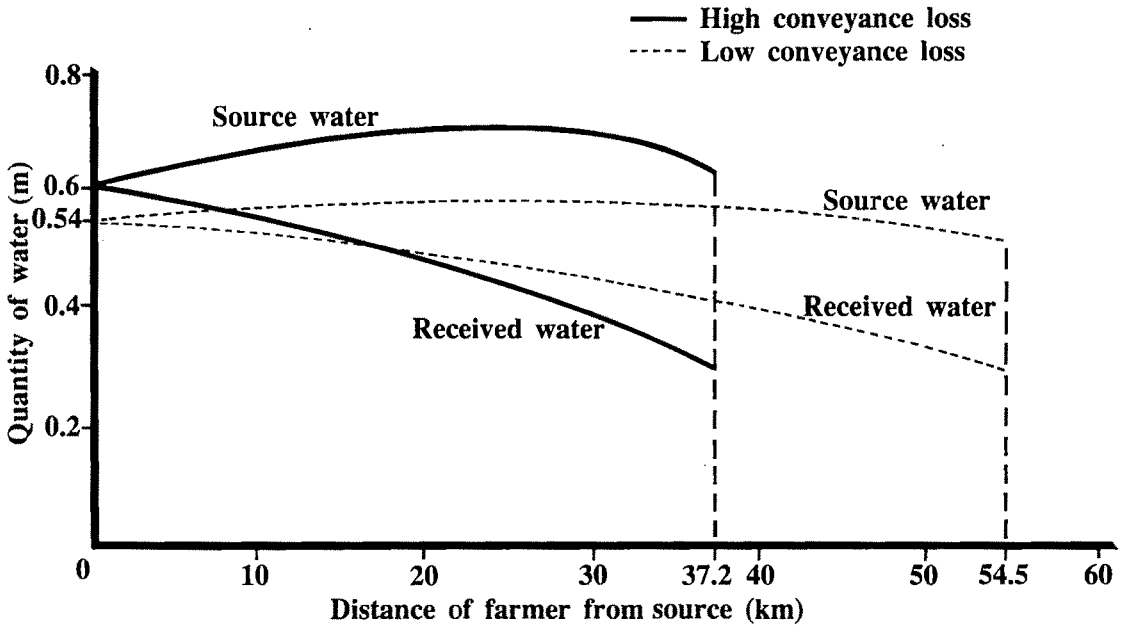

Figure 3. Spatial variation of source water and received water for Pakistan

Table 1. Effect of Alternative Taxation Schemes on Water Charges and Rents for Pakistan (with high conveyance loss)

	Water Charges per Farm (\$)			Rents per Farm (\$)		
	Head	Qmax ^a	L ^b	Head	Qmax	L
Marginal cost pricing	250.1	291.0	262.5	207.2	68.9	0
Proportional benefit taxation	247.0	194.3	141.8	210.4	165.5	120.8
Equal charges	207.8	207.8	207.8	249.6	152.1	54.8
Equal rents	282.2	183.6	86.6	175.0	175.0	175.0

^a Qmax denotes the location where source water allocations are maximized.

^b L denotes the system boundary.

beyond that point get decreasing amounts of source water.⁹

(c) Received water decreases steadily with distance from source (fig. 3). With an increase in conveyance efficiency, the curve for received water flattens, reducing spatial differences in water received. Under high conveyance losses, efficient allocations at the head are approximately double that at the tail.

(d) If farm size is uniform, total water charges under marginal cost pricing are maximized at the point of maximum source water and do not vary substantially over space (table 1).¹⁰ Thus, schemes that charge spatially uniform taxes but ration efficient water allocations (q^*) might be an attractive policy option.

(e) When compared to the other taxation schemes discussed, marginal cost pricing is most inequitable, while proportional benefit taxation permits all farmers to collect a higher degree of rents than if there was no taxation (table 1). The scheme that equalizes net rents across locations benefits farmers located at the tail of the system the most while equalizing water charges provides administrative simplicity.¹¹

Concluding Remarks

In the presence of conveyance losses, efficient spatial allocation of irrigation water implies that the quantity of water applied should fall with distance from the water source. In terms of water produced at the source (before subtracting conveyance losses), the optimal quantity of water allocated to further reaches of the system increases and then decreases with distance from the source.

Under marginal cost pricing, the effective price of water on the farm increases and quasi-rents decrease away from the source. If nonprice instruments for enforcing water allocations are available, then a variety of benefit taxation schemes can be adopted to make the spatial dis-

tribution of rents more uniform, the choice of which depends upon the welfare objectives of the irrigation agency. Water charges that equalize net benefits are vertically equitable but could lead to political pressures for expansion of irrigated area beyond its efficient size. Water charges proportional to net benefits allow higher rents towards the tail of the system, relative to marginal cost pricing, and also preserve horizontal equity and mitigate against rent seeking. Equalizing water charges provides a pragmatic compromise by limiting rents from expansion of the project area, avoiding the additional administrative problems of differential pricing and responding to unfairness associated with paying higher water charges for less total water received.

The model also provides an operational basis for estimating irrigation benefits under alternative allocation rules as the aggregate area under the individual demand curves. Existing methods of estimating irrigation project benefits have largely been based on ad hoc estimates of expected increases in revenues or profits, not on theoretical foundations that take into account the specific characteristics of irrigation systems. The model can also be used to address the concerns of irrigation planners regarding the distribution of benefits and costs in various combinations of allocation rules and financing arrangements.

The benefits of efficient spatial management as described here should be weighed against the higher administrative costs that may be incurred. The model can also be expanded by allowing for the endogenous choice of conveyance and on-farm irrigation technology, and private groundwater extraction. Methods for classifying land quality can also be incorporated (e.g., Caswell and Zilberman). Empirical work is needed to determine the shape of the marginal product schedule under varying environmental conditions. In empirical applications, the framework suggested above can also be extended to estimate the expected benefits of irrigation in different (stochastic) rainfall environments.

⁹ We performed a similar set of computations with data from California and found that a higher marginal product per unit of on-farm water and higher intensity of water use in California contributed to a larger optimal water stock Z^* and higher effective prices. Similarly, the absolute value of rents, as well as head-tail differentials in prices and rents were much larger in magnitude in California than in Pakistan.

¹⁰ In a low conveyance loss regime, the spatial variation in water charges would be still lower, strengthening the case for uniform water charges over space.

¹¹ Under very high conveyance losses, equalizing net rents could result in tail farmers being subsidized for consumption of irrigation water.

Optimal Control of Fish Growth

Oscar J. Cacho, Henry Kinnucan, and Upton Hatch

Fish culture is an efficient means of protein production. However, in contrast to land animals, fish cannot be fed *ad libitum* because feed not consumed within a few hours is decomposed. This paper presents a bioeconomic model for determining cost-effective feeding regimes for pond-reared fish. The interplay among feed allowance, diet quality, and harvest date is explored. The optimal control model used is flexible, incorporates the effects of water temperature on fish appetite, and can be used to gain insight into efficient management of aquacultural production systems in different geographical regions.

Key words: aquaculture, bioeconomics, dynamic optimization, feed efficiency.

Aquaculture is rapidly growing throughout the world. In 1985 it accounted for over 14.5% of total fish landings, an increase of 250% over the preceding decade. In the United States, aquaculture is the fastest growing segment of agriculture, increasing at a rate of over 20% per annum from 1980 to 1987 (Manzi). Fueled by rapidly rising retail prices for fish, low feed cost, production efficiencies made possible by improved understanding of fish biology, and growing consumer preferences for fish, U.S. catfish production has more than quadrupled since 1980 (U.S. Department of Agriculture). Mississippi is the largest producer of farm-raised catfish (with over 75% of the total domestic production), followed by Arkansas, Alabama, and Louisiana (Keenum and Waldrop, U.S. Department of Agriculture).

Fish production has several advantages over land animal production systems. Fish convert feed into body tissue more efficiently than land animals, the ratio of weight gain to feed consumed averages 0.84 for channel catfish, compared to 0.48 for broilers and 0.13 for beef. The proportion of edible lean tissue in the dressed carcass of catfish is .81 compared to .60, .54, and .65 for beef, pork, and chicken, respectively

(Lovell). However, the fact that fish are raised in water poses complications not present in land animal production systems. Loss of nutrients occurs if feed is not consumed immediately. After a few hours, unconsumed feed is decomposed by bacteria. The excess feed represents a wasted resource which, when coupled with the added organic wastes discharged by fish, decreases available dissolved oxygen in the water. Low dissolved oxygen decreases fish appetite and growth rates and increases potential death losses. Reduced water quality also exacerbates off-flavor problems (Kinnucan et al.). Although mechanical aeration can mitigate the effects of reduced dissolved oxygen, production costs are increased.

An important decision faced by fish producers is how much to feed each day (Jensen). The distinction between *ad libitum* and satiation feeding is important. In *ad libitum* feeding, feed is available throughout the day, and the animal decides when and how much to consume. In satiation feeding, as much feed as fish will consume in fifteen to thirty minutes is offered once a day. To avoid the risk of accidental overfeeding, Jensen recommends adjusting the feed allowance every two weeks, and feeding approximately 90% of satiation. Thus, reliable estimates of fish appetite under different environmental conditions are needed.

The advantages of using biological and nutritional information in dynamic production models were discussed by Fawcett and later exploited by Chavas, Kliebenstein, and Crenshaw for swine production; Chavas and Klemme for dairy farms; and Talpaz et al. for broilers. Concerning aqua-

The authors express appreciation to Tom Lovell and two anonymous reviewers for helpful comments on an earlier draft. Responsibility for the final content rests with the authors.

culture, emphasis has focused on the stocking/harvesting decisions for shrimp (Karp, Sadeh, and Griffin), prawn (Leung and Shang), and carp (Talpaz and Tsur). These studies, however, assume that feeding follows a predetermined schedule. The purpose of the research reported in this paper is to develop a model for determining cost-effective feeding regimes for pond-reared fish and to quantify the interplay among feed allowance (ration size), diet quality (protein percent), and harvest date. The research procedure employs an optimal control model based on a fish growth simulator. Catfish is used because of its importance and because experimental data are available to calibrate the growth model.

This paper provides the basis for applying an iterative research process to aquacultural products. Existing research information is integrated to provide insight into further research needs. Results from new research can in turn be incorporated into the model with no need for major modifications of the basic equations that describe the growth of the animal (Allen et al.). A firm-level optimization problem with dynamic and static components is developed. The biophysical model is briefly discussed, and an optimal control model is developed to solve the dynamic portion of the problem. The strategy used in this paper is similar to that of Talpaz et al. for broilers, in that the economically optimum body-weight trajectory is obtained by controlling feed intake.

The Model

In a typical catfish operation, fingerlings measuring 4 to 6 inches are stocked in spring at 2,500 to 5,000 fish per acre. Feed containing 32% protein is offered every day, either to satiation or at a rate of 3% of estimated body weight per day. Water quality, as measured by the concentration of dissolved oxygen (DO), is checked on a daily basis during summer. When DO falls below a critical level (generally 2 ppm.), aeration equipment is used to restore the oxygen to a safe level. Ponds are generally harvested by processors, who prefer fish weighing 0.75 to 1.25 pounds (340 to 568 grams).

The model developed here is concerned with short-run decisions. Therefore, only variable costs are considered. Production costs and returns are expressed on a per-hectare (ha) basis. The producer seeks to maximize return (π) above vari-

able costs per hectare of pond water. Maximize

$$(1) \quad \pi = YP_Y - (C_F + C_A + C_L),$$

where Y is the quantity of fish (kg/ha), P_Y is price of catfish (\$/kg), C_F is feed cost (\$/ha), C_A is aeration cost (\$/ha), C_L is total fingerling cost (\$/ha). The production function is

$$(2) \quad Y = W_H S,$$

where S is stocking rate (fish/ha), and W_H is harvest weight (kg/fish), defined as

$$(3) \quad W_H = W_0 + \int_{t_0}^{t_H} \omega_t dt,$$

where t_0 is stocking day, t_H is harvest day, W_0 is stocking weight (kg/fish), and ω_t is the growth rate on day t (kg/day).

Production costs are defined by

$$(4) \quad C_F = P_F S \int_{t_0}^{t_H} R(t) F_t dt, \quad 0 \leq R(t) \leq 1,$$

$$(5) \quad C_A = P_K \int_{t_0}^{t_H} A_t dt, \text{ and}$$

$$(6) \quad C_L = P_L S,$$

where P_F is price of feed (\$/kg), P_K is price of electric power (\$/kW · hr), P_L is price of fingerlings (\$/fish), R is ration size (relative to appetite), F_t is fish appetite on day t (kg/fish day), A_t is energy used for aeration (kW · hr/ha day).

In addition we have the following technical relationships:

$$(7) \quad F_t = \frac{dF}{dt} = f\{W(t), T(t)\},$$

$$(8) \quad \omega_t = \frac{dW}{dt} = g\{W(t), T(t), R(t), D\},$$

$$(9) \quad A_t = \frac{dA}{dt} = h\{W(t), T(t), R(t), D, S\},$$

where W is fish weight (kg), T is water temperature (°C), and D is diet composition (percent protein). Functions (7) and (8) represent daily input and output, respectively, simulated by a system of fifteen nonlinear differential equations (Cacho). Simulation starts with food intake (7), and follows the energy flow inside an individual fish to estimate growth rate (8). A simplified version of the model is presented in the following section.

The Biophysical Model

In the fish growth model, the energy provided by feed is partitioned into maintenance and growth needs. Daily growth is treated as a residual quantity after maintenance needs are met (Chavas, Kliebenstein, and Crenshaw). Daily growth rate is defined as

$$(10) \quad \omega_t = \phi(DE R F_t - M_t).$$

The term in parentheses represents daily energy gain, and the parameter ϕ is a function of fish body composition that converts energy into weight units. The value of ϕ ranges from 0.33 to 0.86, depending on the proportion of water, protein, and fat in the fish body; DE is the digestible energy content of the ration (fixed at 2,800 Kcal/Kg); M_t is the energy required for maintenance (Kcal/day); and the remaining variables are as previously defined.

Feed intake is the most important factor influencing fish growth. Fish appetite on a given day is defined as

$$(11) \quad F_t = \Omega_T W^{0.7},$$

where

$$(12) \quad \Omega_T = \frac{\Omega_1 T e^{-\Omega_2/T}}{1 + \Omega_3 e^{-\Omega_4/T}}.$$

All the parameters in equations (11) and (12) are positive. Because fish are cold-blooded, water temperature is a major factor affecting all levels of fish growth. Temperature affects early growth, food intake, maintenance requirements, metabolic rates, and the composition of gain (Kau-shik). Ω_T increases from close to zero at 8 degrees centigrade ($^{\circ}\text{C}$) to a maximum of 0.43 at 33°C and rapidly decreases thereafter.

Energy used for maintenance is obtained from dietary protein, fat, and carbohydrates. The latter nutrients are readily converted to fat and stored in that form. Thus maintenance energy (M_t) is defined as

$$(13) \quad M_t = MP_t + MF_t,$$

where MP_t and MF_t are maintenance energy provided by protein and fat, respectively, defined as

$$(14) \quad MP_t = \beta_P R^{\tau_P} \Gamma_T W^{0.8},$$

$$(15) \quad MF_t = \beta_F R \Gamma_T W_K^{0.8},$$

where

$$(16) \quad \Gamma_T = \Gamma_1 e^{\Gamma_2 T}.$$

In (15), W_k represents fish body energy. All the parameters in equations (14) to (16) are positive, and τ_P is greater than 1. β_P , τ_P and β_F are functions of diet composition (digestible protein/digestible energy).

Substituting equations (11) to (16) into (10) yields a growth function that is concave in both ration size and water temperature (with a maximum when $T = 30^{\circ}\text{C}$). This model simulates protein and fat dynamics, allowing for the inclusion of quality attributes into the production function. Coefficient values and other details of the growth model are presented by Cacho.

The expected annual water temperature cycle is described by the function

$$(17) \quad T(t) = T_A + T_R \sin \left(2\pi \frac{t_0 + t - t_A}{365} \right),$$

$$1 \leq t_0 \leq 365,$$

where T_A is the average annual temperature, T_R represents the range of temperature about T_A , t_A is the time of the year at which $T = T_A$, stocking date (t_0) equals 1 on January first, and t is the number of days from stocking to the current day. It was assumed that $T_A = 20^{\circ}\text{C}$, $t_A = 120$ days, and $T_R = 13^{\circ}\text{C}$. This function was added to the model to provide the average daily temperature input; it can be applied to different geographical areas by specifying the appropriate parameters.

Energy used for aeration [equation (9)] is estimated by

$$(18) \quad A_t = \frac{DO_d}{OT_p},$$

where DO_d is oxygen demand (Kg/ha day) and OT_p represents oxygen transfer rate in the pond (kg/kW hr). The oxygen requirements of a fish are given by diet composition and energy used for maintenance. These requirements were estimated from M_t in equation (13), by using oxycaloric equivalents of specific nutrients (Elliott and Davidson). OT_p is defined as (Boyd, Rajendren, and Durda)

$$(19) \quad OT_p = OT_s \frac{\beta DO_s - DO_p}{9.07} 1.024^{T-20} \alpha,$$

where OT_s is standard oxygen transfer rate (kg/kW hr) (provided by the aerator manufacturer); DO_s is oxygen saturation level at actual water temperature, obtained from solubility tables (Boyd); DO_p is the dissolved oxygen level to be maintained in the pond; $\alpha = 0.77$ and $\beta = 0.94$ are correction factors determined by Shelton and

Boyd for Alabama ponds. A value $OT_s = 1.9$ is close to the average for electric paddlewheel aerators (Ahmad and Boyd). $DO_p = 5$ mg/l is assumed because this level will provide enough oxygen without constraining appetite or growth.

The following assumptions were made in solving the optimization problem: (a) Temperature is deterministically given by time of the year as described by equation (17). (b) Feed is purchased in bulk; therefore, diet composition is fixed throughout the growing season. (c) Six thousand 20-gram fish/hectare are stocked on April first. (d) The rate of aeration (A_i) is automatically adjusted in response to the fish oxygen demand to keep the dissolved oxygen level at 5ppm.

The stocking rate assumption deserves comment. Although increasing the stocking density increases total production per unit area (up to the carrying capacity of the pond), the higher stocking increases production risks (Hanson, Martin, and Flynn) and produces greater variability in fish size at harvest. The effects of stocking density on individual fish growth are complex because of the interplay of social interactions (e.g., competition for food and aggression) and the effects of higher biomass on water quality.

Assumption (c), when coupled with assumption (d), represents a conservative approach. The pond environment is maintained as favorable as possible, reducing the risk of losses due to low dissolved oxygen and diseases. These assumptions can be relaxed once more experimental information becomes available to allow their treatment as decision variables in the growth model.

Solution Strategy

By substituting equations (2) through (19) into (1) we can express profit in terms of nine variables. The state variables $W(t)$ and $DO_p(t)$ (endogenous) and $T(t)$ (exogenous) describe the state of the system at any time t . The decision variables t_0 , t_H , $R(t)$, A_i , D , and S can be controlled. $DO_p(t)$ is fixed at 5ppm through adjustment of the decision A_i [assumption (d)]. $T(t)$ cannot be controlled; its trajectory from t_0 to t_H is predetermined by assumption (a). Because S and t_0 are fixed [assumption (c)], the problem is reduced to finding the optimal combination of $R(t)$, D , and t_H . Because fish are fed once a day, time is divided into discrete one-day intervals. We obtain a set of $n = 2 + (t_H - t_0)$ first-order conditions of the form,

$$(20) \quad \frac{\partial \pi}{\partial x_i} = P_F \frac{\partial Y}{\partial W_H} \frac{\partial W_H}{\partial x_i} - \left(\frac{\partial C_F}{\partial x_i} + \frac{\partial C_A}{\partial x_i} \right) = 0, \\ \text{for } i = 1, 2, \dots, n;$$

where $x_1 = D$, $x_2 = t_H$, $x_3 = R(t_0)$, ..., $x_n = R(t_H)$. The complexity of the biophysical model and the presence of nonlinear equations preclude an analytical solution to the problem.

Numerical solution was accomplished in two steps. In the first step, an optimal control algorithm was used to optimize the dynamic decision variable $R(t)$ for different values of the static decision variables D and t_H , and for different terminal values of the state variable $W(t_H)$. Optimal control results were output to a file that, in the second step, was used to find the profit-maximizing solution. The second step can be easily accomplished using a spreadsheet or graphics package.

The Optimal Control Problem

The problem is to find the trajectory of the control variable $R(t)$ that minimizes the cost of producing a fish of weight W_H at harvest time t_H . The objective is to minimize

$$(21) \quad J = P_F \int_{t_0}^{t_H} R(t) F_t dt,$$

subject to

$$(22) \quad F_t = f\{W(t), t\},$$

$$(23) \quad \omega_t = g\{W(t), R(t), t\},$$

$$(24) \quad 0 \leq R(t) \leq 1,$$

$$(25) \quad W(t_0) = W_0, \text{ and}$$

$$(26) \quad W(t_H) = W_H.$$

The functional (J) represents the cost of feeding an individual fish from stocking to harvest. Because P_F is constant for a given diet composition (D), the problem can be reduced to maximize

$$(27) \quad H = -R(t) F_t + \sigma(t) W(t);$$

constraint (24) is introduced by the lagrangean function:

$$(28) \quad \Lambda = H + \lambda_1(t)R(t) + \lambda_2(t)[1 - R(t)],$$

which translates into the optimal control function,

(29)

$$R^*(t) = \begin{cases} 0 \\ R^S(t) \in [0, 1] \\ 1 \end{cases} \quad \text{if} \quad \begin{cases} H_R < 0 \\ H_R = 0 \\ H_R > 0 \end{cases};$$

where

$$H_r = \frac{\partial H}{\partial R}.$$

Here, H_R is the switching function and R^S is the singular path of the control. Bang-bang control occurs when the singular path is outside the allowed bounds (Beltrami, Liu and Forker).

Evaluating the Euler equation for the state W (Burghes and Graham), we obtain the adjoint equation:

$$(30) \quad \frac{d\sigma}{dt} = R(t) \frac{\partial F_t}{\partial W} - \sigma(t) \frac{\partial \omega_t}{\partial W}.$$

Equation (29) implies that along the singular path:

$$(31) \quad \sigma^*(t) = \frac{F_t}{\frac{\partial \omega_t}{\partial R}}; 0 \leq R \leq 1.$$

The adjoint function shows that the shadow cost on a given day is represented by the ratio of fish

appetite to the rate of change in fish growth rate with respect to the control variable.

F_t places an upper limit on the amount of energy that can enter the system on a given day; F_t is determined by temperature and weight (equation 11) and is not affected by the control $R(t)$. For a given state of the system, an increase in the efficiency of feed use will cause a decrease in the shadow cost.

The functions involved in equation (31) are illustrated in figure 1. This figure was numerically generated using equations (10) to (16). Figure 1A shows fish appetite [the numerator of equation (31) or equation (11)] in temperature space at five different fish weights. Four states (I to IV), corresponding to different temperature/weight combinations, were selected to analyze $\sigma(t)$. The shadow cost increases with increasing R (fig. 1B); roman numerals on the curves indicate the corresponding state of the system. At $T = 30$ (states I and III), the increase is nearly linear. At $T = 33$ (states II and IV), the shadow cost increases at an increasing rate. When the system is at a high- T high- W combination (IV), a rapid increase in shadow cost occurs as the control increases, implying a higher pressure to use feed efficiently.

If the differential equation (30) could be solved

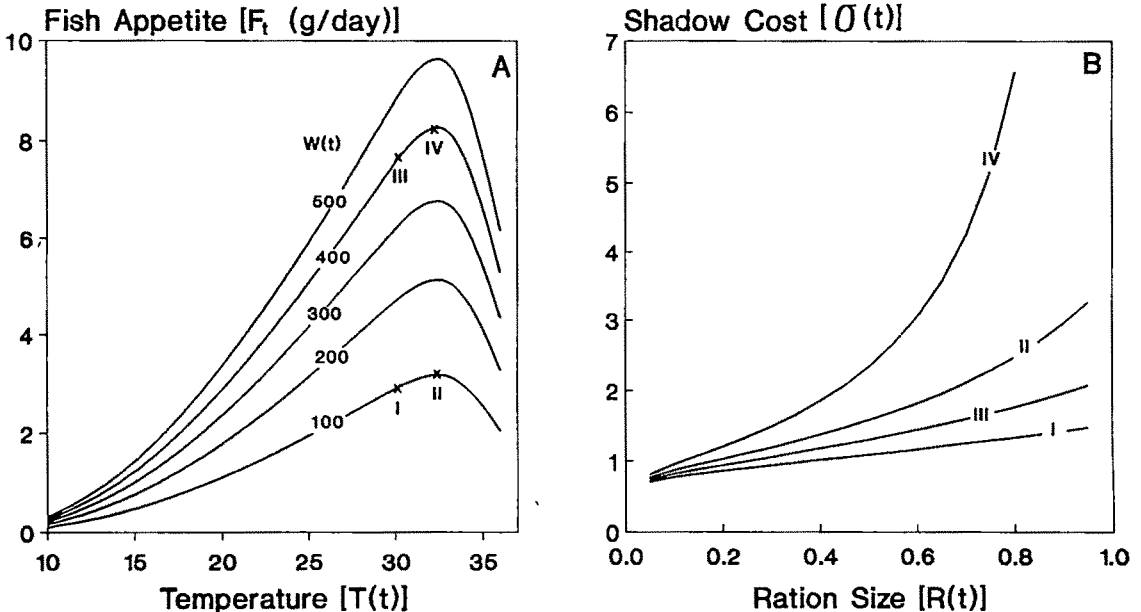

Figure 1. Relationship between the control $R(t)$ and the shadow cost $\sigma(t)$ at four different states of the system (temperature/weight combinations)

for $\sigma(t)$ as a function $R(t)$, the result would be a system of two equations (30) and (31), with two unknowns ($R^*(t)$ and $\sigma^*(t)$). While these equations are useful for gaining insight into the system, numerical solution of the problem is more easily obtained by finding the value of $R(t)$, within the interval $(0, 1)$, that maximizes H in equation (27). Then equation (30) is used to estimate the value of $\sigma(t + 1)$. Solution of equation (30) requires an estimate of the initial value of the adjoint $\sigma(t_0)$. Although $\sigma(t_0)$ is unknown, the final value of the state $W(t_H)$ is known, providing the boundary necessary to solve the system. If the terminal value of the state were open, the transversality condition $\sigma(t_H) = 0$ would apply (Seierstad and Sydsæter). However, in the dynamic version of the traditional cost minimization problem, with $W(t_H)$ fixed, $\sigma(t_H)$ is not constrained.

A shooting algorithm combined with a Brent maximization subroutine (Press et al.) was used for numerical solution. The algorithm consists of estimating an initial value for the adjoint, $\sigma(t_0)$, and numerically integrating equation (30) while maximizing equation (27) at one-day intervals. If the terminal condition in equation (26) is not achieved, $\sigma(t_0)$ is adjusted and the procedure is repeated until $W(t_H) = W_H$ is obtained. At this point the optimal solution for the given set of constraints occurs. For given values of the static decision variables D and t_H , the corresponding functions $R^*(t)$, $\sigma^*(t)$, and $W^*(t)$ represent, respectively, the optimal trajectory for the control, the adjoint, and the state variable.

Results

Optimal Trajectory

Figure 2 shows the optimal trajectories compared to a growth maximization and the feeding schedule recommended by Jensen. A 32% protein diet, the most commonly used by catfish farmers (Keenum and Waldrop), was used to generate these curves. The effects of water temperature on fish appetite and potential for growth are apparent. For the assumed temperature cycle, maximum feed consumed (F_{max}) increases from almost zero to a maximum of 38 kg per ha per day in late summer (fig. 2A). The optimal control path ($R^*(t)F_t$) is a bimodal curve with a local maximum in late spring, a local minimum in midsummer, and a global maximum in late summer. This trajectory minimizes the area un-

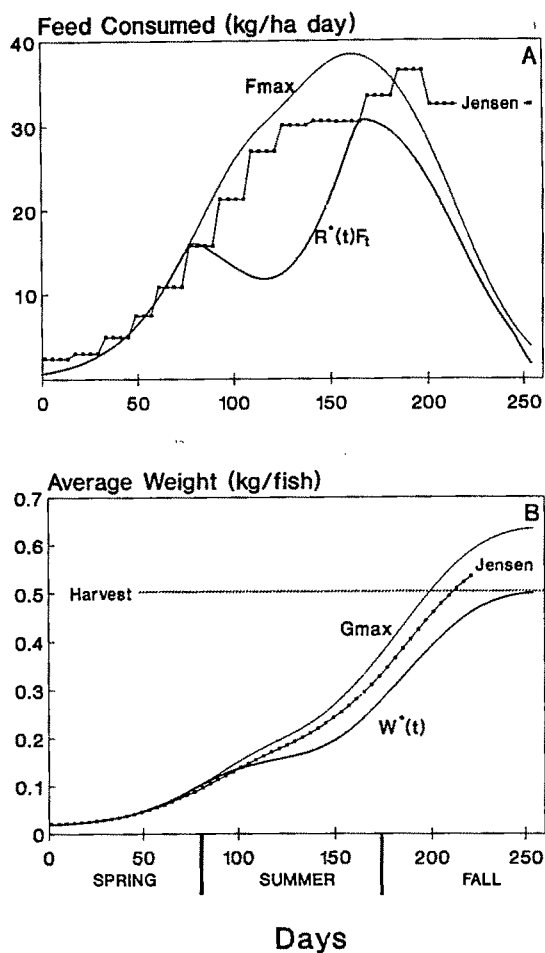

Figure 2. Trajectory of the state variables $T(t)$ and $W(t)$, and the control variable $R(t)F_t$ under optimal control, Jensen's feeding schedule, and maximum growth

der the curve while satisfying the boundary conditions of the problem. The integral of $R^*(t)F_t$ represents total feed necessary to produce a fish of weight W_H on day t_H with a $D\%$ protein diet. The shape of the curve is the same for different values of D , t_H , and W_H ; but the extreme points change. Thus, feed input use is affected by the static decision variables. In contrast to growth maximization, in which fish are fed to satiation, the cost minimization solution implies that feed should be restricted during selected growth periods (see fig. 2A). The restricted feeding regime is consistent with the results for broilers obtained by Talpaz et al. Jensen's stepwise feeding schedule falls between the optimal and maximum trajectories during the summer months.

The fish growth curves (fig. 2B) exhibit three

inflection points. Fish weight increases at an increasing rate during spring; after the first inflection point in late spring, it increases at a decreasing rate in midsummer. The second inflection point occurs in late summer, and fish gain weight at an increasing rate during fall. The third inflection point occurs in late fall, and fish growth rate rapidly decreases as winter approaches. The patterns of growth in the curves shown in figure 1B are caused by the temperature cycle, in concert with the associated feeding trajectory and the changing needs of the growing fish [see equations (11) to (17)]. The optimal path of the state variable, $W^*(t)$, gives the slowest growth rate during summer, followed by Jensen's trajectory. A harvest weight of 500 grams is reached in 198, 210, and 250 days under maximum growth, Jensen's feeding schedule, and optimal control, respectively. Because growth rate is so slow during winter, it is not practical to stock new fish in the fall. Thus, the only benefit of a shorter season is the reduced interest payment.

Isoquant Analysis

The optimal control path was determined for 180 pairs of dietary protein (26% to 42% at increments of 2) and crop length (205 to 250 days at increments of 5) values, at 2 harvest weights (500 g and 600 g). Total feed consumed was estimated by numerically integrating $R^*(t)F_t$. Preliminary analysis indicated that total feed consumed and the initial shadow cost can be approximated by the function:

$$(32) \quad Z = \alpha + \beta_1 C + \beta_2 D + \beta_3 D^2 + \beta_4 CD,$$

where Z represents either $\sigma^*(t_0)$ or total feed consumed (kg/ha), and C represents crop length (days). Results for $\sigma^*(t_0)$ can be incorporated into the optimal control algorithm to provide an initial estimate for a given set of boundary conditions. The regression results for feed consumed can be used to approximate the protein/crop-length pair that minimizes cost, thereby reducing the computational effort involved in finding a global minimum. An iterative procedure can be established, whereby the optimal control algorithm is run at smaller intervals in the neighborhood of the previous approximation.

After analysis of preliminary results, the optimal control solution was obtained for a finer

Table 1. Effects of Crop Length, Dietary Protein, and Harvest Weight on Optimal Control Results

Parameter	$\sigma^*(t_0)$		Feed	
	(harvest weight)			
	500g	600g	500g	600g
α	64.6 (15.71) ^a	375.8 (1.51)	12,089 (40.07)	20,140 (15.09)
β_1	0.027 (1.63)	3.29 (3.26)	-1.34 (1.10)	15.70 (2.91)
β_2	-3.17 (23.58)	-38.43 (4.79)	-411.22 (41.67)	-875.87 (20.37)
β_3	0.055 (51.86)	0.98 (16.04)	5.58 (71.28)	14.91 (45.78)
β_4	-0.0026 (5.52)	-0.12 (4.12)	-0.10 (2.90)	-0.85 (5.47)
R^2	0.98	0.81	0.99	0.98
N	128	122	128	122

Note: estimated coefficients for equation (32).

^a The absolute value of t -ratios are shown in parentheses.

grid of static decision variables, with t_H ranging from 228 to 254 at two-day increments, and D ranging from 31% to 39% at 0.5 increments, and for harvest weights of 500 and 600 grams. Final regression results for equation (32) are presented in table 1. All the coefficients are significantly different from zero ($P < 0.05$), except α for the shadow cost at 600 grams and β_1 for feed at 500 grams. Both variables are convex in dietary protein.

Isoquants were obtained by plotting total feed consumed against the corresponding dietary protein value for a given crop length (fig. 3). Points on these isoquants can be used to find the cost-minimizing level of protein for a given price situation. The actual distribution of feed through the growing season can then be obtained by running the optimal control algorithm. Three points are worth noting: (a) The shape of the isoquants indicates that feed quantity and quality are substitutes in production within a certain range. As the protein content of the diet increases, the amount of feed necessary to obtain a given weight decreases almost linearly between 31% and 34% protein. This is equivalent to Chavas, Kliebenstein, and Crenshaw finding that corn and soybeans are substitutes in swine production. (b) As crop length increases, the amount of feed needed decreases, implying that feed is more efficiently converted into animal tissue by delaying the marketing date. (c) High dietary protein has negative effects on growth of larger fish, as indicated by the isoquants for a 600-gram fish curving upward. This result is also consistent with the findings by Chavas, Kliebenstein, and

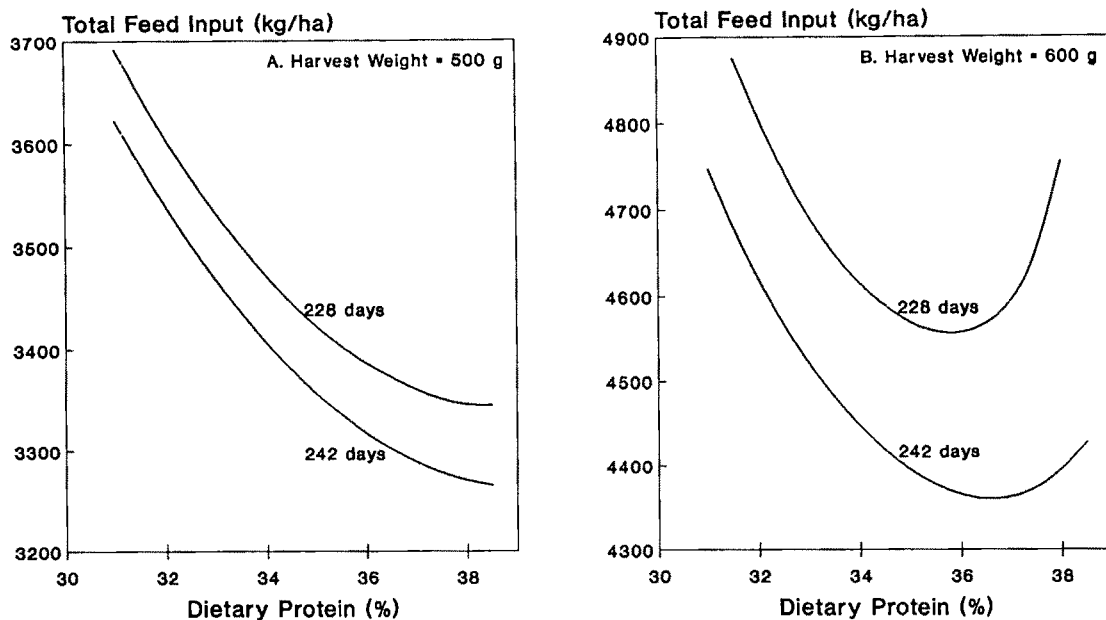

Figure 3. Feed-protein isoquants derived from optimal control results

Crenshaw, where optimal dietary protein decreased as pigs grew larger.

Price Sensitivity

Feed price was determined by the function

$$(33) \quad P_F = \delta_1 + \delta_2 \cdot DP,$$

where P_F is feed price (\$/Kg), and DP is dietary protein content (Kg protein/Kg feed). The intercept represents the nonprotein cost of feed. Its value will be affected by changes in the costs of marketing and processing, as well as by the prices of grains (mainly corn) and fats that provide dietary energy in catfish feeds. The slope of equation (33) represents the protein cost of feed. Its value will be affected by the prices of soybean and fish meal, the two main sources of protein in catfish diets. Both δ_1 and δ_2 can be represented by a probability density function. However, because it is assumed that feed is purchased in one installment at the beginning of the season, these parameters are treated as given.

The coefficients in equation (33) can be estimated from prices of catfish feeds of different protein contents. Alternatively, data can be generated for different diets by a least-cost formulation for a set of ingredient prices. Using the latter method, Reutebuch estimated $\delta_2 = 0.543$; $\delta_1 = 0.112$ was algebraically estimated assum-

ing a cost of \$260 per ton for a 32% protein diet (Crews and Jensen).

Table 2 presents the sensitivity of optimal static decisions to changes in input prices. Dietary protein and crop length that maximize return above variable costs (discounted at 12%) are shown. Optimal protein ranges between 32% and 36.5%. For a given set of prices, optimal protein values are lower for the higher harvest weight. This result suggests the possible benefit of allowing diet composition to become a dynamic decision variable. Interest rate has practically no effect on optimal protein. Energy price has a slight effect on optimal protein, where higher prices are associated with higher protein. This result is not surprising because the demand for energy is related to feed allowance, and higher dietary protein requires lower feeding rates (see fig. 3). Optimal crop length ranges between 232 and 252 days. As expected, crop length is negatively related to interest rate, although the effect is small. Feed and energy prices are positively related to crop length, indicating that they increase pressure to use feed more efficiently (i.e., reduce the amount of feed per unit of weight gain, see fig. 3).

Table 3 shows the ratio of profit obtained with an optimal control trajectory over that obtained with a growth-maximizing strategy (assuming a catfish price of \$1.43/kg or \$0.65/lb). Profit ratios range from 1.02 to 1.27. At base feed

prices, profit can be increased by 14% and 5%, respectively, for 500-gram and 600-gram fish by following an optimal trajectory.

Concluding Comments

An optimal control formulation of the decision problem about catfish feeding under aquacultural conditions yields several insights useful for defining more effective production regimes. The key findings are summarized as follows:

(a) In contrast to current industry practices, the optimal control solution suggests fish should be "starved" during periods in which water temperatures are high. Reducing feed intake during the hot summer months improves the efficiency of feed conversion without impairing fish health. Further, restricting the diet helps maintain water quality and may reduce the incidence of off-flavor.

(b) The cost-minimizing feed trajectory differs from the growth-maximizing trajectory, both in terms of total quantity of feed and feeding pattern. At a farm price of \$0.65 per pound profit can be increased by as much as 27% (depending on feed prices) by following an optimal trajectory as compared to growth maximization. The differences suggest significant profit advantages to producers who pursue economic rather than biological optima.

(c) The differences between biological and economic optima lessen as the harvest weight of the fish increases. Thus, the allocative error arising from feeding the fish to satiation (as would be required for growth maximization) may become less important if processors prefer larger fish (over 600 grams liveweight). Currently processors favor 340 to 568-gram fish (Jensen).

(d) Optimal dietary protein ranges from 32% to 36.5%, depending on nutrient prices. The current industry standard is 32% protein (Keenum and Waldrop), and it is not changed in response to price changes. Isoquant analysis suggests that benefits can be attained by allowing dietary protein to change during the growing season.

(e) At base interest rates (12%), the optimum harvest date for 500-gram fish ranges from 238 to 246 days after stocking. Optimum harvest date for a 600-gram fish ranges from 244 to 252 days. As feed price increases, optimal crop length increases, reflecting the pressure to improve feed conversion efficiency by feeding at a reduced rate over a longer time period.

(f) Further development of the model presented here can produce valuable management

aids for fish producers. Additional research is needed concerning the effects of population density and dissolved oxygen on fish appetite and metabolism. Such information would permit stocking density and aeration rate to be treated as decision variables.

Farm Production Decisions Under Cross and Conservation Compliance

Dana L. Hoag and Herb A. Holloway

The success of soil conservation compliance (CC) hinges on participation in commodity programs. Using mixed integer programming, the profitability of participation in commodity programs was examined on seventeen surveyed North Carolina farms. Without CC, cross compliance in commodity programs increased projected soil erosion by over 80% when participation increased from 30% to nearly 90%. With CC, erosion fell by two-thirds at the high participation level but decreased by only 1% with low participation. Individual farm acreage base and crop yield strongly affected the profitability of CC. Compliance is increasingly profitable on farms with more base acreage and higher yields.

Key words: conservation compliance, cross compliance, North Carolina, soil erosion.

Congress passed several programs in the 1985 Food Security Act to reduce soil erosion on U.S. cropland (Glaser, Ervin). One program, conservation compliance (CC), requires producers to have a plan for applying appropriate conservation measures on highly erodible land. Producers without such a plan are ineligible for most government farm program benefits (e.g., deficiency payments and commodity loans). The conservation plan must be developed by 1990 and fully implemented by 1995. A related program, conservation reserve, offers annual rental payments and cost sharing for removing highly erodible lands from production for ten years.

While CC may be effective in removing commodity program incentives to use erosive farming methods, its impact on soil erosion is limited to program participants. The effectiveness of the conservation reserve is also limited because only farmers in conservation compliance may collect rental payments.

One of the factors influencing the effectiveness of conservation compliance in reducing soil erosion is the costs of implementing a conservation plan relative to commodity program benefits. The net impact of CC on participation costs

will be highly site-specific depending on soil type, climate, historical production, current acreage base, and other farm-level characteristics. These variables and others determine whether CC raises or lowers program participation and, hence, how it affects soil erosion.

Soil erosion may increase where CC leads to lower participation rates in farm programs. Battie and Sappington found that the majority of farmers in a Tennessee watershed would not find it profitable to comply with a hypothetical cross-compliance program. Therefore, erosion might increase if the program were imposed. However, erosion levels could fall if cropping restrictions imposed by commodity programs have led to the production of erosive crops. Producers who no longer participate in farm programs may turn to less erosive crops.

The objective of this analysis is to determine how farm-level variables such as acreage base and average yield affect the impact of conservation compliance on farm profits. Key factors influencing participation were determined by comparing optimal net returns with and without commodity programs on seventeen North Carolina farms. Mixed integer programming (MIP) was used to optimize program participation-crop mix decisions. Perry et al. demonstrated the usefulness of MIP in modeling farm programs but did not examine conservation compliance.

Other researchers have examined the conservation reserve program (Reichelderfer and Boggess, Young and Osborn, Hertel and Preckel) and conservation compliance (Barbarika and

Dana L. Hoag is an associate professor, and Herb A. Holloway is a former research assistant, Department of Agricultural and Resource, Economics North Carolina State University.

The authors are grateful for comments and assistance provided by Douglas Young, Randy Rucker, and three anonymous *Journal* reviewers.

Dicks, Huang, Richardson et al.). However, the methodology used here reveals how farm characteristics such as program base and land productivity affect compliance incentives with detail not possible in a macrolevel analysis (Barbarika and Dicks, Huang) and with variety not possible in a case-farm or composite-farm analysis (Richardson et al., Wollenhaupt and Blase). Batie and Sappington examined the impacts of only a hypothetical cross-compliance program on Tennessee farms and did not identify the impacts of farm characteristics or distinguish between commodity program cross-compliance and conservation compliance.

The magnitude of CC's impact on crop production or soil erosion in the United States is not estimated here. Nevertheless, this study shows how certain farm characteristics may alter the effectiveness of CC in preventing soil erosion, thus indicating what it will accomplish. This study also shows how conservation compliance can fail to completely remove or out-compete continued incentives from commodity programs to use erosive farming systems.

Conservation Legislation

The conservation reserve program (CRP) provides annual rental payments for ten years on highly erodible land retired from production. Producers also receive 50% cost sharing to establish a vegetative cover. Acres entered into CRP reduce a farm's cropland base by the ratio of CRP to all cropland on the farm. Crop base is used to determine commodity program benefits.

The conservation compliance provision revokes eligibility for U.S. Department of Agriculture (USDA) farm program benefits to anyone producing an "agricultural commodity" on "highly erodible land" without an approved conservation plan. These benefits include price and income supports, disaster payments, crop insurance, Farmers Home Administration loans, Commodity Credit Corporation storage benefits, farm storage facility loans, and other programs under which payments are made for commodities produced by the farmer.

Highly erodible land is defined as having an erodibility index (EI) greater than or equal to eight ($EI = RKLS/T \geq 8$). The tolerance level T is the erosion level thought to maintain cropland productivity. The $RKLS$ factors measure the vulnerability of soil to erosion, as described in the universal soil loss equation, based on rain-

fall (R), erodibility (K), slope length (L), and slope gradient (S) (Wishmeier and Smith).

A producer with highly erodible land can obtain a conservation plan that will allow him to continue receiving program benefits by requesting one from the Soil Conservation Service (SCS). To facilitate the implementation of conservation compliance, the SCS developed standardized Alternative Conservation Systems (ACS). These systems are designed to meet conservation compliance requirements without extensive field visits (Ervin, Johnson and Clark). Landowners may select an ACS, which may differ by county and by soil capability subclass, or they can develop a customized plan with the assistance of SCS personnel.

The ACS establishes an allowable erosion guideline. A customized plan can be any combination of practices that reduces annual erosion rates to a comparable level provided by any of the ACS's. The customized plan must have a "CP" product less than or equal to the highest CP product of any of the pre-approved alternative conservation systems. The C (cover management) and P (supporting practice) factors measure the erosiveness of a particular system. When combined with the erodibility of the land, $RKLS$, the CP product indicates the erosion rate of a given system on a given soil.

Production Under Commodity and Conservation Programs

In the absence of government programs, net returns equal crop sales minus production costs. Commodity programs complicate production decisions through price and income supports and with cross-compliance cropping restrictions and temporary acreage set-aside requirements (Glaser). Under cross compliance, producers who receive program payments cannot produce program crops such as wheat or corn on more than their allotted base less an acreage set-aside. Base is the historical acres planted to a crop and set-aside is base acreage with no crop production for one year. Only nonprogram crops such as soybeans, hay, and sunflowers can be produced on more land than a producer's base. Therefore, the commodity programs effectively restrict crop production on both base and nonbase acreage.

A producer incurs at least two kinds of opportunity costs when using commodity programs. First, cropping restrictions may force production of less profitable crops on nonbase acres. Second, a temporary set-aside often is re-

quired in which no production is allowed. In return, the farmer effectively receives a guaranteed income for crops on his base acres equal to his farm or county's program yield times a target price (table 1).

The influence of program requirements on crop mix and other farm decisions can make production decisions complex (Perry et al.). However, conservation compliance and the conservation reserve make production decisions even more complicated. Conservation reserve adds rental payments, reduces base acreage and subjects a grower to a penalty if he fails to comply with conservation compliance over the ten-year period. To reduce erosion, CC adds new restrictions on crop type and production technology to those already imposed by cross compliance. Furthermore, conservation structures may be required and transactions costs are increased because a conservation plan must be filed. This added complexity increases the chance that conflicting production signals will be offered by cross compliance and CC.

The Model

A mixed integer programming model was used to determine optimal participation and cropping solutions for seventeen case study farms in Stanly County, North Carolina. A simplified version of the MIP tableau is given in table 2. The tableau represents a single farm unit as recorded by the Stanly County Agricultural Stabilization and Conservation Service (ASCS). Some farmers operate multiple farm units, but each is treated as a single entity by ASCS. Each farm has a

historical program acreage base in corn, wheat, or other crops.

Participants' farms have established program yields for each crop on which payments are made or they use a county average yield. The program yield is assumed equal to the average crop yield on the study farm for this analysis. Yield estimates by field were based on the distribution of soil mapping units by field and their relative productivity.

The model maximizes net returns to land, risk, and management for a single year by selecting the most profitable combination of cropping systems on each field on each farm while meeting appropriate constraints (table 2). A zero-one conservation compliance activity switches the CC program and commodity program constraints on and off. MIP can be used to solve endogenously for optimal cropping decisions when choices involve binary constraints. In this case, cropping decisions affect CC, which turns erosion and cross-compliance constraints as well as deficiency payment program benefits on or off.

The tableau in table 2 is divided into an objective row, blocks of constraint rows, and columns of input and output activities. Constraint blocks are defined for land use, commodity programs, soil erosion, equipment use, and returns from crop sales and CRP rent. The activities include conservation compliance (0 for compliance, 1 for noncompliance), specialized equipment use (integer), crop production, crop sales, CRP rents, and deficiency payments. Production is delineated by field because each has a unique productivity and susceptibility to soil erosion. For simplicity, only one piece of equipment, two crops, and two fields are depicted in table 2.

In the objective row (1), the costs of equipment use are added to annual operating costs of all crops on all fields and to the annual cost per acre of land enrolled in the Conservation Reserve Program (CRP). Returns include crop sales from all fields, CRP rental payments, and deficiency payments.

Production is constrained in row 2 such that all crops on all fields plus CRP acreage does not exceed available cropland. Rows 3 and 4 assure that the production on any field does not exceed its acreage. Rows 2, 3, and 4 will contain slack if the farmer is in conservation compliance because some land will be set aside. However, these constraints are binding when the producer does not comply or participate in commodity programs.

Table 1. Price and Program Assumptions for the Average and Forecasted Model Scenarios

	Static Scenario ^a	Forecasted Scenario
Corn market price	\$2.60/bu.	\$2.23/bu.
Corn target price	2.84	2.75
Corn set-aside	10%	10%
Wheat market price	3.57	3.26
Wheat target price	4.10	4.00
Wheat set-aside	10%	5%
Oat market price	2.20	1.83
Oat target price	1.49	1.44
Oat set-aside	10%	10%
Soybean market price	6.85	6.22

Static scenario sets all variables equal to the 1988 levels, and the forecasted scenario is based on FAPRI forecasts.

Table 2. Simplified Tableau of Mixed Integer Programming Model for Cross- and Conservation Compliance Decisions

Row	CC 0 = Comply 1 = Out	Equip. use (Integer)	Field 1			Field 2			Crop Sales			CRP		Deficiency Payment		RHS
			Crop 1 (ac)	Crop 2 (ac)	CRP (ac)	Crop 1 (ac)	Crop 2 (ac)	CRP (ac)	Crop 1 (\$/bu)	Crop 2 (\$/bu)	MP1	MP2	Rent (\$/ac)	Crop 1 (\$/ac)	Crop 2 (\$/ac)	
1 Objective		-OC	-PCI	-PC2	-C	-PCI	-PC2	-C					R	DP1	DP2	MAX
2 Land use			1	1	1	1	1	1	1							≤A
3 Land use			1	1	1	1	1	1								≤A1
4 Land use																≤A2
5 Commodity program	B												B/A	1 (1 - SA1)	1 (1 - SA2)	≤B
6 Commodity program	-M		1 (1 - SA1) -1	1 (1 - SA2)	1	1 (1 - SA1) -1	1 (1 - SA2)	1								≤A
7 Commodity program														1		≤0
8 Commodity program															1	≤0
9 Erosion (CC)	-M		CP	m	0											≤L
10 Erosion (CC)	-M					0	0	1								≤0
11 Equipment		-U	H1	H2		H1	H2									≤0
12 Crop sales			-Y1	-Y2		-Y1	-Y2		1	1						≤0
13 Crop sales																≤0
14 CRP rent					-1			-1					1			≤0

Note: This example includes only two crops and field combinations and only one type of equipment. Actual farms contained many fields, with several cropping options. Variables names:

- CC Conservation compliance
- OC Annual ownership cost of equipment
- PC Per acre operating cost, crop 1, crop 2
- MP Market price/unit, crop 1, crop 2
- DP Deficiency payment/acre, crop 1, crop 2
- M An arbitrarily large number
- m M/A
- SA Set aside rate for crop 1 or crop 2
- B Sum of all base acreage
- CP Product of "C" and "p" erosion factors per acre
- L "CP" limit under CC on field 1
- A Total crop acreage
- A1, A2 Acres in field 1 or 2
- U Maximum available hours of equipment use
- H Hours of equipment use on per acre of crop 1 or 2
- Y Yield per acre of crop 1 or 2
- C Conservation reserve program cost per acre
- R Conservation reserve program rent per acre

Commodity program and CRP constraints are defined in the commodity program block, rows 5–8. If a producer is participating in commodity programs and therefore in CC, column 1 is set to zero and row 5 requires that the deficiency payments are not paid on more acres than the base, less set-aside and CRP adjustments, allows. However, if a farmer does not participate, column 1 is set to 1 and constraint 5 would not allow the model to select any positive amount of crops with deficiency payments or CRP.

In row 5, CRP acreage reduces available base at a rate equal to $CRP / (\text{total cropland acres})$ as required by law. Base is reduced through the CRP rent column as the program enters CRP acres. For example, 100 acres of CRP on a 400-acre farm with 100 acres of corn base would reduce the base by 25% ($100/400$) to 75 acres. Program crops consume base at a rate of $1/(1 - SA)$, where SA is the annual set-aside requirement ranging from 0 to 1.0. Each acre of program crop would utilize 1.25 acres of base with a 20% set-aside ($1/(1 - .20)$); therefore, 60 acres of corn would require 75 acres of base. Program crops are constrained by a producer's current base and restrictions from CRP enrollment.

The crop and CRP base acreage reductions are contained in a single constraint. Base swapping is allowed among program crops to meet conservation compliance (ASCS). Therefore, only the total base, equal to all crop bases less CRP reductions, is constrained.

Row 6 assures that available cropland is not exceeded when a producer participates in the programs. If a producer does not participate, the compliance variable becomes 1, which when multiplied by the large negative number ($-M$), relaxes the constraint. Rows 7 and 8 require that an acre of production, with its associated costs, be brought into production for each acre of deficiency payment earned.

The erosion block is controlled by the conservation compliance integer variable. It is non-binding when a producer does not wish to receive deficiency payments or enroll land in CRP. When the constraint is binding, the CP factor of a crop system is limited to the maximum allowed by CC on the field where the crop is produced. Erosive systems that are not permitted on highly erodible fields are excluded by assigning them an arbitrarily large number, m , in the erosion block. For example, cropping system 2 is not allowed on field 1 and thus an m is entered in row 9. However, the same system is allowed on field 2 because the field is not highly erodible and erosion is not constrained.

Similarly, CRP is allowed on field 1 but not on field 2 because field 2 is not highly erodible.

In the intermediate run, equipment ownership costs are variable. Therefore, the cost of specialized equipment that changes between cropping systems was added into the tableau. Equipment was allowed to enter only in whole units. Therefore, each piece of equipment was more costly if it was not used to its full capacity. A unit of equipment relaxes the equipment constraint by the number of hours it can be used in a single year, U . Each acre of crop consumes these hours at a specific rate, H . When the constraint is binding, another whole unit of equipment is needed to allow more production.

In the final block, CRP acres are transferred into rent and yield is transferred from the field to sales activities. Yields were allowed to vary by field for each crop based on the soil types within the field.

A Case Study

A case study in Stanly County, North Carolina, is used to examine the impact of CC and commodity programs on net returns and soil erosion. The net returns to program participation with and without CC and under two levels of program benefits and price expectations were compared across seventeen actual farms. Net returns were optimized using mixed integer programming (MIP) for each farm.

This study is micro-oriented because returns are maximized on individual farms with a unique base acreage, soil productivity, number of fields, and size of operation. The most profitable combination of crops, production technology, and participation is solved field by field for each farm. However, the study also provides information about the broader impacts of CC by comparing the results of the seventeen farms to determine which characteristics influenced the participation decision, soil erosion, and net returns.

Data and Assumptions

The seventeen sample farms were selected from a randomly drawn data set for the Piedmont region of North Carolina. Stanly county is one of three counties drawn by lot. Each county had a probability of being selected equal to its relative share of corn production to all counties being considered in the region. Thirty-six farms were selected from those that had corn base recorded

in the Stanly county ASCS files. Samples were chosen randomly in four farm-size categories: 20–50 acres, 51–100 acres, 101–250 acres, and more than 250 acres. No effort was made to identify additional farms operated by the producer listed; thus, each farm number was treated as an independent entity. The final seventeen farms chosen reflected a variety of base, farm size, and soil productivity (table 4).

ASCS field maps were compared with soil survey maps made by the Soil Conservation Service (SCS) to determine the proportions of various soil types in each field. These estimates were combined with yield and erosion information to compute weighted average yields and erodibility for each field. Of 133 fields on the seventeen sample farms, 18% were highly erodible, 79% were potentially highly erodible. Only 3% were slightly erodible. SCS in North Carolina considers all potentially highly erodible soils highly erodible unless contested by the producer; then a field visit to measure slope is required. Therefore, the majority of fields in Stanly County are classified as highly erodible.

The Stanly County SCS provides farmers with a list of five alternative conservation systems (ACS) from which to choose (table 3). Farmers are free to choose from the list or to develop a customized system with a *CP* factor less than ACS's maximum *CP* factor. Stanly County does not offer any conservation structures such as terracing under any of their ACSs. However, a farmer could choose such a system if it reduces erosion by as much as the most erosive ACSs.

Enterprise budgets were developed for the ACSs and for commonly used systems that would not qualify under CC. Net profitability of a system equaled gross production returns less the variable production costs. Yields varied by field according to soil type. Production costs did not vary by field.

Farmers who participate in CC are required to establish and maintain permanent vegetative cover on all "critical areas" (determined by SCS).

Critical areas are draws or other areas where concentrated water flow increases the risk of soil erosion. They account for an estimated 6% of a typical field in North Carolina (B. Brock, North Carolina SCS, personal communication 1988).

Commodity prices and program provisions used in the MIP model were taken from the *FAPRI Review* (Food and Agriculture Policy Research Institute). Two scenarios were used: (a) a static scenario, where expected commodity prices, target prices, and set-aside requirements equal current levels; and (b) a forecasted scenario, where commodity prices, target prices, and set-aside requirements are equal to an average of the 1989/90 through 1994/95 FAPRI predicted prices (table 1).

Farmers are free to reallocate their existing acreage bases among most program crops (except cotton) on a one-time basis to meet the requirements of a conservation plan. For example, a corn base of 100 acres could be traded for 50 acres of wheat base and 50 acres of corn base. The 1988 bases for the seventeen North Carolina farms ranged from 32% to 100% (table 4).

Deficiency payments and CRP rental payments were the only government benefits considered. It is difficult to value other program benefits and these other benefits are little used in Stanly County. For example, in 1988, only one farmer used federal crop insurance; only five farmers bought crop insurance in 1989 (following a drought). The Farmers Home Administration issues only about five production loans annually.

Results

The MIP model optimizes returns for each farm under the following scenarios which have been designed to compare the impacts of cross and conservation compliance with various price and program scenarios: (a) static prices and programs without conservation compliance, (b) static

Table 3. Stanly County Alternative Conservation Systems

Number	Soils	Year 1	Year 2	CP-Factor ^a

prices and programs with conservation compliance, (c) forecast prices and programs without conservation compliance, (d) forecast prices and programs with conservation compliance.

Participation and Net Returns

Program participation and net returns for each farm under each scenario are shown in table 4 and table 5. The farms are ordered in table 4 on the basis of increasing proportions of base acreage to total crop acreage. Participation is more profitable as base increases under all four scenarios

but is relatively less profitable with CC. Farms 14, 16, and 17, which have a relatively large share of program base, profit from participation under all four scenarios, and farms 1 and 2, which have very little base acreage, are always better off not to participate. The profitability of participation on the other farms is affected by the scenario under which the model is run; that is, whether price and program benefit expectations are high or low.

Farms that have a high ratio of base to non-base acreage have relatively more benefits to protect than other farms but face similar costs to adopt conservation technology since all highly

Table 5. Effect of Conservation Compliance on Net Returns, Commodity Program Payments, and Erosion on All Seventeen Stanly County Farms

Scenario	Use Commodity Programs ^a (No. Farms)	Net Returns (\$)	Commodity Program Payments (\$)	Soil Erosion (CP-factor)

% change	-53	-8.3	-31.2	-64.6%

^a Number among the seventeen farms participating in commodity program.

erodible fields on the farm must have a conservation plan. In addition, farms with a high average yield have more program benefits to protect. Therefore, farm losses stemming from CC, equal to net returns before CC minus net returns after CC, were regressed on the relative farm base (*FB*) and corn yield (*CY*). The results yielded a strong relationship as follows:

$$NR = -32.47 + 0.17(FB) + 0.32(CY),$$

(5.66) (4.00)

where *NR* is the difference in net returns, before and after CC, the terms in parentheses are *t*-values, *FB* is base/(crop acreage), and *CY* is the bushels of corn yield per acre; R^2 is 0.76. There is a positive relationship between both average yields and the proportion of base with the net farm losses stemming from CC. Producers possessing relatively small amounts of base can minimize losses from CC by discontinuing participation in commodity programs. However, those farmers with larger bases stand to lose more from CC either by sacrificing more program benefits if they do not comply or by adopting the necessary conservation measures. Farms already not participating did not realize any change in net returns (table 4). The overall effect on net returns for all seventeen farmers was an average reduction of 1.3% with static expectations and 8.3% with forecasted expectations (table 5).

Farmers' expectations about prices and program benefits influence program participation. Without conservation compliance, five farms (29%) maximized profits by participating in commodity programs under the static scenario, whereas fifteen farms (88%) maximized profits with program participation in the forecast scenario (table 5). The difference can be attributed to higher deficiency payments for all crops, a lower wheat set-aside rate, and a lower market price for oats under the forecasted scenario.

Under conservation compliance, participation in commodity programs is reduced in both scenarios, from 29% to 18% (5 to 3) and 88% to 41% (15 to 7) in the static and forecast scenarios, respectively (table 5). The lower commodity prices in the forecast scenario increase the benefits and lower the costs of conservation compliance. Therefore, program participation is higher under that scenario with or without conservation compliance.

Overall, deficiency payments to all seventeen farms were six to ten times higher under the forecast scenario compared to those under the static scenario (table 5). CC reduced deficiency

payments by 58% in the static scenario and 31% in the forecast scenario.

Fifteen of seventeen farms participated in commodity programs under the forecast scenario without CC, and four of these had some CRP acreage (Holloway). Conservation compliance caused eight of these farms to discontinue participation in the commodity programs. Six of these eight placed or increased acreage in CRP. The other two participated neither in CRP nor in commodity programs. Farms placing acreage in CRP must meet CC requirements on all of their fields, even though some no longer participate in commodity programs. For some of these farms, it was more profitable to take land out of production and put it into CRP than to plant it to a conservation crop. For others, it was more profitable to expand acreage beyond that allowed by their base, thus disqualifying them for commodity benefits (cross compliance) but allowing them to retain CRP benefits if crops produced on other fields were not erosive.

Soil Erosion

Soil erosion is affected indirectly on base and nonbase land through cross-compliance restrictions on cropping alternatives. For example, corn is a highly profitable crop that can be produced on base, and soybeans is the most profitable crop allowed on nonbase land. However, corn and soybeans can be highly erosive compared to wheat or wheat doubled cropped with soybeans. Therefore, the commodity programs can increase erosion on base land when corn is made more profitable than less erosive crops, and they can increase erosion on nonbase land by substituting erosive soybeans for small grains.

In Stanly County, the commodity programs increased soil erosion as described above. The forecast scenario provided greater program benefits than the static scenario and led to greater participation and soil erosion. As shown in table 5, without CC the total level of soil erosion on all seventeen farms was more than 80% higher under the forecast scenario than under the static scenario (381 compared to 210). The participation rate in commodity programs was about three times higher (15 compared to 5). However, because more farmers participated in commodity programs under the forecast scenario, CC was much more effective in reducing erosion (64.6% compared to 1.4%).

The potential of cross compliance to increase erosion is highly site specific. In a Missouri

study, for example, the most profitable crop, with or without programs, was found to be soybeans. Therefore, commodity programs would not necessarily encourage additional erosion on non-program lands because continuous soybeans would have been produced anyway (Wollenhaupt and Blase).

Concluding Comments

One of the factors influencing participation in future commodity programs is the cost of conservation compliance (CC) compared to the benefits of the commodity programs. Of the seventeen North Carolina farms reviewed, participation dropped by as much as half when conservation compliance was required. Actual sign-up rates for conservation plans have been high (Brock). These plans, however, require no immediate action and yet enable farmers to participate in the commodity program through 1995. Therefore, they may not accurately reflect actual intentions.

This analysis indicated that acreage base and soil productivity will have a substantial impact on program compliance. Farms with relatively little base acreage and relatively low yields likely will find it more costly to participate in commodity programs under CC than to quit using the programs altogether. Because all highly erodible fields need conservation plans, these farms have relatively less benefits to protect but face similar costs to comply.

The impacts of two program restrictions, cross compliance and CC, were examined. Cross compliance tended to increase soil erosion by restricting program crops to base acres. This forced farmers to produce more erodible and less profitable crops on nonbase acres. In Stanly County, continuously tilled soybeans were the most profitable crop allowed on non-base land and were more erosive and less profitable than soybeans double cropped with wheat. Double cropped wheat and soybeans requires base, however. Cross compliance increased erosion by over 80% when participation increased from about 30% of farms to almost 90% under the static and forecast scenarios, respectively. Conservation compliance more than offset the increase, however.

Across all farms examined, net farm income fell by 1% to 8% under CC depending on price and program expectations. Commodity program payments fell by 31% to 58%. Conservation compliance incentives to reduce soil erosion competed with the erosion-inducing effects of

cross compliance. Soil erosion declined by only 1% in the static price and program expectations scenario because commodity programs were not sufficiently attractive to induce producers to adopt needed conservation measures. A larger decline of 64% occurred in the forecast scenario because benefits were more attractive and therefore compliance remained stronger.

These results demonstrate how firm-level studies can provide insight that national studies may miss. Often the information gathered about the expected impact of a policy in aggregate analyses will not provide as much detail about individual farm impacts as models of the firm can reveal. Policy makers may find additional information similar to that provided here useful in dealing with individuals who are disproportionately affected by a given policy.

Measuring the Economic Efficiency of Producing Rural Road Services

Steven C. Deller and Carl H. Nelson

The research reported here examines the ability of a sample of Midwest township officials to produce low-volume rural road services in an economically efficient manner. Farrell-type measures of input use and scale efficiency are reported. Results suggest that over 50% of costs may be unnecessarily incurred because of input use inefficiency. Correlation between output measures and the efficiency measures suggests that larger jurisdictions are more efficient than smaller jurisdictions. In addition, 84.5% of the townships exhibit technology characterized by increasing returns to scale. These results suggest that jurisdictional consolidation of production-related responsibilities may yield substantial cost savings.

Key words: managerial efficiency, rural governments.

The efficient allocation of resources by local government remains an important issue, especially given the small scale of operation inherent to many rural governments. At issue is the ability of local public officials to control costs in the face of shrinking revenue sources. The research reported in this article provides some empirical evidence on the economic efficiency of a sample of small rural governments in the Midwest (Illinois, Minnesota, and Wisconsin) vested with rural road responsibilities.¹ Farrell-type measures of efficiency are computed for managerial and scale efficiency in order to test the ability of local public officials to provide rural road services in a least cost fashion.

The paper contains six sections. The first section describes managerial and scale efficiency within a public setting. The concepts of efficiency reference sets and efficiency measurement are then discussed. The network of low-

volume rural roads is then described, followed by the empirical results. The concluding section considers the study's policy implications.

Efficiency within a Public Setting

One view of local government maintains that the small-scale operation is inherently inefficient and costly (Chicoine and Walzer 1985, Bish and Osrom). Arguments are made that the physical consolidation of small government units would increase production efficiency, thus better utilizing available resources (Baumel and Schornhorst, Mercier). The consolidation argument traditionally hinges on scale economies in production. Indeed, empirical tests have generally indicated that scale economies are present in the production of public goods and services (Doeksen and Peterson, Fox).

A complementary argument addresses the ability of small, particularly rural, governments to develop an effective service provision program (Cigler; Reid 1984, 1986; Reid and Sullivan; Sokolow). The managerial capacity of smaller units of government to effectively perform functions is questioned. Managerial inefficiencies, if present, incur additional costs and exacerbate potential fiscal constraints. While the proponents of consolidation appeal to the notions of poor managerial skills and size economies, arguments about managerial efficiency

¹ The sample is limited to three states to preserve homogeneity in institutional arrangements and topography.

are limited to logical speculation (Sullivan and Reid).²

This study evaluates the efficiency of local governments by employing the tools of modern production economics and efficiency measurement. The Farrell method requires a normative criterion (e.g., cost minimization or profit maximization) to judge individual observations. Individual observations are then compared to these normative efficient reference sets. Measures of efficiency then can be correlated with relevant policy-related variables. Of particular interest in this study is the relationship between township size and efficiency.

The traditional consolidation literature has almost exclusively examined technical relationships between governmental organization and the supply of public goods. Because demand considerations are ignored, the traditional empirical work supporting governmental consolidation may not be sufficient. This research is concerned solely with the examination of efficient production of local public goods. The vital distinction between provision and production must be maintained when addressing policy considerations.

The Structure of Economic Efficiency

To compute the managerial and scale measures of efficiency, a technical definition of the efficient reference sets must be established. Scale efficiency refers to the location of the observed input combination relative to the scale efficient output level associated with constant returns to scale.³ Färe, Grosskopf, and Lovell (FGL) suggest that one measure of scale efficiency compares the distance between the boundary of the input requirement set for the given observations and the boundary of the input requirement set associated with constant returns to scale.

To calculate this measure FGL suggest the

construction of two functions which map inputs and outputs onto the real number line:

$$(1) \quad F(y, x) = \min_{\lambda} \{\lambda \in R_+ | \lambda x \in V(y)\}, \quad \text{and}$$

$$(2) \quad W(y, x) = \min_{\lambda} \{\lambda \in R_+ | \lambda x \in V^c(y)\}.$$

Here $y \in R_+^m$ represents a vector of outputs, $x \in R_+^n$ represents a vector of inputs, $V(y)$ represents the subset of all input vectors which yield at least y , and $V^c(y)$ is the input requirement set under constant returns to scale.⁴ The functions give the maximum amount by which an input vector can be radially decreased without altering the given output level. The difference between the two functions is the structure imposed on technology: the function $F(y, x)$ is constructed on an unrestricted technology whereas $W(y, x)$ is constructed on a technology exhibiting constant returns to scale.

The measure of scale efficiency is the distance between the boundary of $V(y)$ and $V^c(y)$, or

$$(3) \quad S(y, x) = W(y, x)/F(y, x).$$

If $S(y, x) = 1$, the unrestricted technology is identical to the constant-returns-to-scale technology, and the combination (y, x) is scale efficient. If $S(y, x) < 1$, then the technology yielding $F(y, x)$ has characteristics different from the technology yielding $W(y, x)$, and the combination is scale inefficient. Note that $S(y, x) \geq 1$ because $V^c(y)$ being a subset of $V(y)$ implies $W(y, x) \leq F(y, x)$.

To construct a measure of managerial efficiency, information is required about the goals of local public officials. Given an Inman view of local governments, a reasonable normative criterion is cost minimization.⁵

The cost-minimizing set of input vectors at input prices w , where prices are strictly positive, and outputs y is defined as

$$(4) \quad CM(y, w) = \{x \in V(y) | w'x = C(y, w)\},$$

² The presence of scale economies does not imply the presence of managerial inefficiencies, i.e., capacity shortfalls. The traditional test for scale economies implicitly assumes away the capacity issue because no estimate is made of the resources wasted or costs incurred because of poor management practices. If costs are increased as a result of managerial shortfalls, the traditional empirical tests for scale economies may be capturing capacity-induced costs and incorrectly attributing them to scale economies.

³ The use of output levels associated with constant returns to scale as a reference set is consistent with the traditional consolidation literature which searches for the minimum of the long-run average cost curve.

⁴ The input correspondence is assumed to satisfy the following axioms (Shepard): (a) impossibility of free production; (b) the input correspondence is bounded for any x ; (c) inputs are strongly disposable (monotonicity); (d') $V(y)$ is closed; and (e) strong disposability of outputs. See Färe, Grosskopf, and Lovell for measures of efficiency under alternative assumptions.

⁵ Inman's view of local governments may be modeled as a two-step process. The first step corresponds to provisionary decisions (demand or public choice), while the second step refers to production related decisions. Given that most local officials operate in the second step, a reasonable criterion may be to produce the demanded level of the public good at the lowest possible costs, i.e., cost minimization.

where the cost function $C(y, w)$ is defined as

$$(5) \quad C(y, w) = \min_x \{w'x | x \in V(y)\}.$$

If an input combination x yielding output level y is not in the cost-minimizing reference set, it is considered managerially inefficient.

Farrell suggests that a natural measure of managerial efficiency is the ratio of minimum and observed costs:

$$(6) \quad O(y, x, w) = C(y, w)/w'x.$$

If $O(y, x, w) = 1$, then the observed input combination is consistent with cost minimization and the observation is managerially efficient. If $O(y, x, w) < 1$, then the observed input combination is inconsistent with cost minimization.

Empirical Methods

Following Farrell, Shephard, Afriat, and FGL, a nonparametric representation of the relevant efficient reference sets is employed in this research. An alternative approach relies on statistical methods to estimate a parametric representation of the relevant set (Førsund, Lovell, and Schmidt). The nonparametric method is employed because of its handling of multiple outputs and its computational ease relative to the parametric method.

Mathematical programming methods construct a piece-wise linear reference technology from a sample of observations. Allow M to denote the matrix of observed outputs and N the matrix of observed inputs. Assuming that the axioms on technology hold, the reference technology can be expressed as

$$(7) \quad V(y) = \{x | zM \geq y, \quad zN \leq x, \\ z \in R_+^k, \quad y \in R_+^m\}$$

where the vector $z = (z_1, \dots, z_k)$ denotes the input utilization rate, or intensity level, k is the number of observations, and m is the number of outputs.

Afriat, Koopmans, and later Grosskopf have shown that alternative structures can be placed on technology by imposing various restrictions on the vector of intensity parameters. Specifically, by requiring z_i to be non-negative, as in (7), constant returns to scale is imposed. [Thus, for notational consistency, $V(y)$ in (7) should be expressed as $V^c(y)$]. By imposing $\sum_i z_i = 1$ and $z \in R_+^k$, increasing, decreasing, or constant returns are allowed; and imposing the restrictions

$\sum_i z_i \leq 1$ and $z \in R_+^k$ limits technology to non-increasing returns to scale.

The computation of the scale efficiency measure requires solution of (1) and (2), or the solution of the linear programming problems

$$(8) \quad F(y, x) = \min_{\lambda, z} \{\lambda | zM \geq y; \quad zN \leq \lambda x; \\ \sum_i z_i = 1; \quad z_i \geq 0\}, \text{ and}$$

$$(9) \quad W(y, x) = \min_{\lambda, z} \{\lambda | zM \geq y; \\ zN \leq \lambda x; z_i \geq 0\}$$

for each observation. The ratio of the solutions to the LPs (3) provides a scale efficiency measure for each observation.

Computation of managerial efficiency requires the solution to (4) and (5), or the solution to the linear programming problem

$$(10) \quad C(y, w) = \min_{x, z}^* \{w'x^* | zM \geq y; \\ zN \leq x^*; \quad \sum_i z_i = 1; \quad z_i \geq 0\}$$

for each observation. By construction, the solution to (10) is the minimum cost of producing output y at prices w , $C(y, w)$, and $O(y, x, w) = C(y, w)/w'x$.

The measure of managerial efficiency can be interpreted as a percentage cost reduction that could be achieved. This is because the cost of employing the observed input combination, x , given factor prices, w , is $w'x$, the cost of employing the cost-minimizing combination is $C(y, w)$, and by construction, $C(y, w) = \lambda w'x$. Thus, λ is the percentage of actual cost at which the observed output could have been produced. Conversely, one minus λ is the percentage reduction in costs that could be achieved by eliminating managerial inefficiency. A similar argument applies to scale efficiency.

Sources of managerial efficiency gains will be investigated by comparing radial and nonradial measures of technical efficiency. The radial technical efficiency measure is the solution to

$$\min_{\lambda, z} \lambda,$$

subject to

$$zM - y \geq 0$$

$$zN - \lambda x \leq 0$$

$$\sum_j z_j - 1 = 0$$

$$z_j \geq 0 \quad j = 1, \dots, k,$$

$$\lambda \in [0, 1].$$

The nonradial technical efficiency measure is the solution to

$$\min_{z, \lambda_1, \dots, \lambda_n} \sum_{i=1}^n \lambda_i / \sum_{i=1}^n \delta(x_i),$$

subject to

$$zM - y \geq 0$$

$$zN - \lambda \odot x \leq 0$$

$$\sum_j z_j - 1 = 0$$

$$z_j \geq 0 \quad j = 1, \dots, k$$

$$\lambda_i \in [0, 1] \quad i = 1, \dots, n,$$

where $\delta(x_i)$ is equal to one if $x_i > 0$, zero otherwise, and \odot denotes component-wise multiplication of the λ and x vectors.

The radial measure constructs a reference isoquant and shrinks the observed input level, x , along a ray from the origin, until it touches the isoquant. The nonradial measure constructs a reference isoquant and shrinks the observed input level x by reducing each component of x as much as possible while remaining on the isoquant. These measures are significantly different when the reference isoquant has segments that are parallel to one of the coordinate axes, as in the case of Leontief technologies. The radial measure simply shrinks observations until they lie on such an isoquant. The nonradial measure shrinks observations until they reach the corner of Leontief-type isoquants. Examining each computed λ_i yields insight into the sources of inefficiency.

Low-Volume Rural Roads

Low-volume rural roads are the responsibility of township and/or county governments. In several midwestern states, townships provide and maintain the basic road network, while counties are responsible for a network of overlapping higher service routes. In the United States, approximately 14,400 towns and townships are responsible, on average, for thirty-eight miles of low-volume roads (Chicoine, Walzer, and Deller). The typical county, however, is responsible for ten times the mileage. The small scale of operation at the township level provides the motivation for considering jurisdictional consolidation for low-volume rural roads.

Five studies have examined scale economies

in producing road services. Swanson studied the costs of providing low-volume township road services in Illinois. Lamb and Pine studied scale economies of rural road services in Kansas, while Leshner and Mapp examined costs of producing county road services in New York. More recently, Deller, Chicoine, and Walzer and Chicoine, Deller, and Walzer examined cost structures of low-volume rural road services in the Midwest. Each found some evidence of scale economies in the production process. While each study has specific limitations, none considered managerial efficiency.

Scale efficiency measures calculated under an incorrect assumption of managerial efficiency will be biased because the two types of efficiency are confounded. If input use is inefficient, then unbiased measurement of size efficiency requires that managerial inefficiency be removed from the data.

The data used for this study are from a mail survey of township officials in three midwestern states (Illinois, Minnesota, and Wisconsin) (Chicoine and Walzer 1984). The sample contains 295 rural jurisdictions from Illinois, 127 rural Wisconsin jurisdictions, and 24 rural Minnesota jurisdictions, for a total sample size of 446 independent observations.

A representative township in the three-state area is responsible for 49.2 miles of road; the largest township has 126 miles of road, and the smallest only four miles. The distribution of road surface types reflects the rural environment: 46.9% of total mileage is gravel, 39.8% is low bituminous, and 13.3% is high bituminous.⁶ The economic difference of surface types is evident from maintenance costs: a mile of gravel road requires approximately \$1,890 annually, while a mile of high bituminous requires \$4,889 annually (Walzer and Chicoine). To allow for the heterogeneous nature of low-volume rural roads, a multiple output model is specified where output is the miles of gravel, low, and high bituminous roads.

Following Deller, Chicoine, and Walzer and Chicoine, Deller, and Walzer, four inputs are used in the production of low-volume rural roads: labor, road graders, single-axle trucks, and surfacing material. The labor input is the number of full-time-equivalent employees. Graders and trucks are measured by number employed. The material input is composed of the amount of sur-

⁶ Bituminous roads are constructed with crushed rock and oil. High bituminous roads are a higher service level and are generally more durable than low bituminous roads.

facing material purchased by the township on an annual basis. All input levels are observed directly from the mail survey.

Prices for each input are available from several sources. The price of labor came from the mail survey and is measured as an average annual salary. Prices for the two capital items were based on a fixed proportion of replacement cost. Replacement costs for these items were determined first by depreciating new equipment prices to reflect the age of the equipment owned by the township. Then, proxies of capital prices were assumed to equal a fixed proportion of the depreciated values based on schedules of average annual equipment expenses. The price of a unit of surfacing material is based on engineering estimates of material requirements for resurfacing projects. To account for spatial differences, the capital and material prices were adjusted using regional cost-of-living indexes.⁷

Empirical Results

Calculation of the scale, cost, and technical efficiency measures described above required the solution of four sets of 446 linear programming problems: one set to calculate $F(y, x)$, one to calculate $W(y, x)$, one to calculate the nonradial measure $[NR(y, x)]$ and a final set to calculate $C(y, x)$. For spatial considerations, townships were grouped by mileage, and subsample means of the two measures of efficiency are reported for each mileage category.

Turning first to managerial efficiency, the typical township contained in this sample exhibits a low degree of managerial efficiency ($O(y, x, w) = .3488$) (table 1). Only eleven townships were identified as perfectly efficient in input use [i.e., $O(y, x, w) = 1.000$].⁸ Only minor variation occurred across the state-grouped subsamples, but significant variation occurred across size-grouped subsamples. The Farrell method

suggests that the typical township may significantly reduce operating costs if cost minimization is achieved.

Insight into the potential cost reductions is provided by the two measures of technical efficiency reported in table 2. Based on a computed F -statistic ($F = 3.95$), there appears to be a significant difference between the radial and nonradial measures of technical efficiency in the case of rural roads (table 2). In every case, this difference was caused by the nonradial measure shrinking labor usage more than the radial measure.

Because capital items are typically expected to be used in fixed proportions, it was surprising to find that the radial-nonradial difference is always caused by the labor variable. That is, the reference isoquant is parallel to the labor axis, and the nonradial measure always shrinks labor usage more than the radial measure.

The radial-nonradial difference is small at large mileages and large at small mileages. This suggests that smaller townships employ too much labor to provide road maintenance services, while larger townships do not. Differences in the quality of labor or tasks assigned to employees do not contradict this result because the averaging of townships over size categories should "average out" heterogeneity in quality and/or job assignments. Similarly, this result is not weakened by possible problems in the measurement of input prices because neither measure of technical efficiency is dependent on price data. Thus, the evidence is strong and robust that smaller townships may experience cost inefficiencies because of excessive labor, while larger townships (i.e., more than 75 miles of road) do not employ excess labor, on average.

Turning to scale efficiency, the typical township contained in this sample was identified by the Farrell method as scale inefficient [$S(y, x) = .6912$] (table 3). Based on these computations, 53 townships (11.9% of the total sample) were scale efficient and 16 townships (3.6% of the sample) exhibited decreasing returns to scale. The remaining 377 townships (84.5% of the sample) exhibited increasing returns to scale, and smaller townships were more scale inefficient than larger townships. These measures of scale efficiency suggest that jurisdictional boundaries that limit the scale of production may increase operation costs unnecessarily.

While the evidence provided by the efficiency measures suggests that larger road jurisdictions may be more cost effective, the statistical significance of the difference in efficiencies has not

⁷ For more detail on input prices see Deller, Chicoine, and Walzer; Chicoine, Deller, and Walzer.

⁸ Following Varian, a simple nonparametric pretest of the data identified eleven townships as cost rational. Five of the eleven townships identified by the Varian pretest were identified as input use efficient using the Farrell approach.

These observations may constitute outliers in the data. To test the sensitivity of the computed measure of overall efficiency, these eleven observations were removed from the sample. The recomputed measure of overall efficiency for the typical township increased to .4745. A simple test of sample means suggests that this increase may be significant ($F = 22.38$). However, the basic policy conclusion remained unaltered.

been established. A test of subsample mean equivalence (F -test), a nonparametric test of central tendency (median test), and several nonparametric tests which compare the distribution (Wilcoxon, van der Waerden, and Savage tests) of the measures across the subsamples were conducted. The results of these tests, reported in table 4, indicate significant differences across all mileages, except for the radial measure of technical efficiency. The strong positive relationship between size and overall efficiency supports the reform traditionalist hypothesis that larger townships are more efficient.

The impact of combining two average size townships can be examined using simple regression analysis. Based on the regression equations reported in table 5, a typical township with 23.1 miles of gravel roads, 19.6 miles of low bituminous roads, and 6.5 miles of high bituminous roads, has an expected overall managerial efficiency of .3608. If the production responsibilities

of two such townships were combined, the expected level of overall input use efficiency is .6184, an increase of nearly 42%. The positive statistical relationship between road mileage and managerial and scale efficiency further supports the increased efficiency of larger townships in producing road services.

Concluding Comments

The empirical evidence from a sample of mid-western townships suggests that larger townships are more efficient than smaller townships. In particular, smaller townships appear to employ an excess amount of labor. Efficiency measurement shows that over 50% of costs may be unnecessarily incurred by the typical smaller township because of managerial inefficiency. In addition, only 11.9% of the sample of townships were identified as scale efficient (i.e., exhibiting constant returns to scale), and 84.5% of the sample exhibited increasing returns to scale.

The correlation between efficiency and township size is strongly positive, and a simple regression of output levels on the measures of efficiency suggests that increasing jurisdictional size increases efficiency. These results suggest that substantial cost reductions could be realized by restructuring rural road maintenance.

These results should not necessarily be used to promote the physical consolidation of smaller jurisdictions into larger, more economically efficient units because they address only production efficiency. Provisionary impacts of consolidation have not been examined. Therefore, a responsible policy prescription supported by these results is consolidation of production responsibilities, something considerably short of jurisdictional consolidation.

^a Number in parentheses is the standard error of the estimate.

One means of production consolidation is contractual agreements between jurisdictions. Smaller units would preserve provisionary authority in arranging the terms of any agreement, but production responsibilities would belong to a larger, more efficient unit. Alternatively, smaller units may cooperate in contracting a private firm to produce the public good. Or, an engineer may be jointly hired by a union of local units to perform production related activities using public resources. Arrangements for more efficient allocation of rural road maintenance labor should be investigated because current allocation is highly inefficient.

Dietary Effects of the Food Stamp Program

Barbara Devaney and Robert Moffitt

Based on data from the 1979–80 Survey of Food Consumption in Low-Income Households, this paper estimates the effects of changes in cash income and the food stamp benefit on household nutrient availability, while controlling for two potential sources of selection bias. The major finding of the empirical analysis is that the estimated dietary effects of changes in food stamp benefits are considerably larger than those resulting from changes in cash income, with estimates of the ratios of the MPC for the food stamp benefit to the cash-income MPC ranging from three to seven across nutrients. No significant evidence of selection bias was found, and the estimated dietary effects of food stamp benefits from the selection bias models are similar to those from the basic model estimated by ordinary least squares regression.

Key words: food stamp benefits, marginal propensity to consume, nutrient availability, selection bias.

The objective of this paper is to assess the dietary effects of the Food Stamp Program (FSP). Despite a substantial literature on the food expenditure and dietary effects of the FSP, empirical results reported in the various studies differ. The study addresses the extent to which the FSP raises the quality of diets of participating households.¹ A related question is the marginal effect of food stamp benefits on diet quality. That is, what are the dietary effects of an additional dollar of benefits, and do coupon benefits affect diet quality more than equivalent cash income?

Model

It is assumed the household chooses from J foods Q_j , $j = 1, \dots, J$, and a composite nonfood good C . The utility function is

$$(1) \quad U(Q_1, Q_2, \dots, Q_J, C).$$

Barbara Devaney is a senior economist, Mathematica Policy Research, and Robert Moffitt is a professor, Department of Economics, Brown University.

This research was funded by the Food and Nutrition Service of the U.S. Department of Agriculture and contract FNS-53-3198-5-47. Any opinions expressed herein are those of the authors and not of the Food and Nutrition Service, Mathematica Policy Research, or Brown University.

The authors gratefully acknowledge the thoughtful comments of Steven Cole, Tom Fraker, and three anonymous reviewers. Any remaining errors are the responsibility of the authors.

¹ The discussion here presumes that one overall measure of household diet quality is available, although a variety of dietary outcome measures have been used in previous analyses of the FSP.

Let Y be total cash income, excluding food stamp benefits; B , the food stamp benefit; and P_j , the price of food good j relative to the price of C . The budget constraint can be written as

$$(2) \quad Y + B = \sum_{j=1}^J P_j Q_j + C.$$

In other words, income plus food stamp benefits is spent on the J food goods and nonfood consumption.

Maximizing utility subject to the constraint on household resources leads to J different demand functions for the food goods which can be written in the form:

$$(3) \quad Q_j = f_j(P_1, P_2, \dots, P_J, Y, B), \quad j = 1, \dots, J.$$

Cash income (Y) and food stamp benefits (B) are entered separately into the demand functions to allow for different effects of changes in cash income and the food stamp benefit levels on food consumption.

To include nutrients in this model, assume that there are K nutrients N_k , $k = 1, \dots, K$, and that each unit of food good yields a_{kj} of nutrient N_k . The K nutrient equations can be written as follows:

$$(4) \quad N_k = \sum_{j=1}^J a_{kj} Q_j, \quad k = 1, \dots, K.$$

Equations (3) and (4) constitute the "true" model of the determinants of nutrient levels. An increase in income or the food stamp benefit, for example, increases the quantity of each food good consumed (Q_j), though some may fall if they are inferior goods. An increase in a food good raises the availability of each nutrient in household diets, the amount depending upon the magnitudes of the a_{kj} 's.

Econometric Estimation

The usual approach to estimating the model depicted by equations (3) and (4) is to focus on the food good demand functions, (3). Most commonly, these individual food-good equations are aggregated to a total food expenditure equation by multiplying the Q_j in each food-good equation by its price and adding them up across goods. However, an equation for total food expenditures does not allow the use of equation (4) to determine the nutrients from food because there is no exact relationship between an increase in total food expenditures and an increase in each of the nutrients; the relationship depends upon the combination of the individual foods embodied in the rise in food expenditures.

Another approach to estimating the theoretical model has been to estimate relationships between nutrient levels and household food expenditures. This is essentially a recursive model in which cash income and the food stamp benefit are assumed to affect household food expenditures, and household food expenditures influence nutrient availability levels. The effects of the FSP, for example, are then traced through their impacts on food expenditures which, in turn, affect nutrient availability levels. However, this approach leads to model specification bias since there is no fixed relationship between household food expenditures and each nutrient; that is, it is generally not possible to use equations (3) and (4) to derive equations with nutrient availability on the left-hand side and total food expenditures on the right. Specifically, the coefficient on total food expenditures in a nutrient equation would represent only some undetermined combined effect of income and food stamps benefits on nutrient levels.

This specification bias could have serious consequences for the estimation of the effect of food stamps on nutrient levels. When the food stamp benefit is entered separately into food expenditure equations, the results of past studies suggest that changes in FSP benefit levels have

a stronger effect on food expenditures than do changes in the level of money income (Chen, Smallwood and Blaylock). It is, therefore, likely that increases in food stamp benefits also have different effects on the consumption of individual food items than do increases in money income. In this case, the food expenditure coefficients in the nutrient equations will represent biased estimates of the effect of the food stamp benefit on nutrient levels, because those coefficients will only represent average effects of increases in money income and in the food stamp benefit.

Adding variables for income, for the food stamp benefit or FSP participation, or both, to the nutrient equations does not reduce the specification bias. In fact, the degree of bias probably increases because there is no reason for food expenditures to remain in the equation after income and FSP benefit variables are added directly.²

Proposed Estimation Procedure

Given the problems with estimating the nutrient equations with aggregate food expenditures in place of the individual food items, the major issue is how to estimate the dietary effects of the FSP. Because there are hundreds of individual food goods and thousands of a_{kj} 's the data do not allow the direct estimation of the individual food consumption equations. However, substituting the individual food demand equations (3) into the nutrient equations (4) results in a set of reduced-form nutrient equations of the form,

$$(5) \quad N_k = g_k(P_1, P_2, \dots, P_j, Y, B).$$

In the reduced-form equations, nutrient levels are related to prices, the food stamp benefit level, cash income, and other variables affecting the demand for food goods. Recognizing that price levels are generally constant for cross-sectional data, a linear regression equation of the form

$$(6) \quad N_{ki} = \alpha_k + \beta_k Y_i + \delta_k B_i + X_i \phi_k + \epsilon_{ki}$$

can be estimated for each nutrient k , where " i " denotes household i , Y_i is household cash income, B_i is the food stamp benefit, X_i is a set of other variables thought to affect the demand

² In addition to these difficulties, entering food expenditures on the right-hand side of the nutrient equations in (4) would lead to a type of simultaneous-equations bias, as food expenditures are endogenous. Therefore, the coefficient on food expenditures in a nutrient equation will be biased upwards.

for food goods and, hence, nutrients, and ϵ_{ki} is an error term. Coefficients β and δ represent the combined effects of (a) the effect of income and the food stamp benefit on the demand for food goods and (b) the effect of food consumption on nutrient levels. The two effects cannot be separated out, but this is unnecessary when determining the effects of the FSP. The important point is that the coefficients correctly capture the effects of income and food stamp benefits on nutrient availability working through the hundreds of individual food goods, even though those individual food consumption levels are not used in the estimation.

Equation (6) is straightforward and simple to estimate using ordinary least squares (OLS) regression. It is based on a framework in which food consumption decisions depend on income, prices, and other factors, and nutrient availability is a byproduct of the food consumption decisions.

Data and Empirical Results

The data used in this report are from the 1979–80 Survey of Food Consumption in Low-Income Households (SFC-LI). This survey was conducted from November 1979 through March 1980 using a national probability sample of approximately 2,900 low-income housekeeping households eligible to receive benefits under the FSP.³ Detailed information on household food use was collected by the SFC-LI. Household food use refers to food and beverages used from household food supplies during the seven days preceding the interview. Food purchased with cash, credit, or food stamps and food that was home-produced, received as a gift or payment for work, or received through other food programs are all included in the measure of household food use. In addition to the data on food use, information was obtained on household characteristics related to food use, such as participation in the FSP, participation in other food assistance programs (School Lunch, School Breakfast, and WIC), household consumption, income, education and employment of the household heads, urbanization, and tenancy.

Data on household food energy and nutrient availability are calculated from the quantity of each food item used from household food sup-

plies. Caloric and nutrient contents of each food item are obtained from tables of the nutritive value of foods. Total household availability of food energy and nutrients is derived by summing the food energy and nutritive values of the individual food items used. Nutritive values pertain to the edible portion of the food used from household food supplies, with some adjustments for vitamin losses during preparation.

Household nutrient availability data from the SFC-LI are based on food used from household food supplies. Nutritive values are not available for food eaten away from home. If the number of meals eaten away from home differs among groups of households, differences in nutrient availability will be observed regardless of whether or not any differences exist in the nutritive value of food used at home. Therefore, an adjustment for the proportion of meals eaten at home is needed when comparing nutrient availability from food used at home by subgroups of low-income households.

Table 1 shows the means of the major variables used in the empirical analysis. Eleven major nutrients were examined, and each is scaled by the number of equivalent nutrition units in the household. The number of equivalent nutrition units (ENUs) is one measure of household size and is defined as the number of adult equivalent males eating meals from household food supplies. It adjusts actual household size for both the age-sex composition of family members and guests and the proportion of meals eaten at home during the designated week. The adjustment procedure weights each household by (a) the nutritional requirements of the member relative to the nutritional requirements of an adult male aged 23–50, where the nutritional requirements are based on the 1980 Recommended Dietary Allowances (RDA) for each nutrient, and (b) the proportion of meals eaten at home during the week. This second part of the weighting scheme is necessary for analyses of nutrient availability since, as noted above, such nutrient data are based only on food used at home. Thus, the ENU adjustment is required not only for the differing age-sex compositions of each household but also because only food used at home is measured.

The income variables shown in table 1 are scaled by the number of adult male equivalents (AME), based on the 1980 RDA for food energy.⁴ Cash income is about eight times larger

³ Housekeeping households contain at least one person having 10 or more meals from household food supplies during the 7 days preceding the interview.

⁴ AME, rather than ENU, is used to scale the independent variables in the analysis because household size in equivalent nutrition units may be an endogenous variable since it depends on the proportion of meals eaten at home.

Table 1. Means of the Variables Used in the Analysis (N = 2,925)

Variable	Mean Value
<u>Nutrients per ENU per day^a</u>	
Food energy (Kcal)	3,988
Protein (g)	129
Vitamin A (IU)	11,414

^a ENU is equivalent nutrition units, which is the number of equivalent adult males eating from household food supplies.

^b AME is number of equivalent adult males in the household.

^c Includes zeros for nonparticipants.

than the average FSP benefit overall. However, the average weekly food stamp benefit per AME for participants only is \$10.84, which is roughly 28% of cash income for participating households (not shown).

The other variables shown in table 1 indicate that, on average, \$2.83 per adult male equivalent per week was from foods received either through the school nutrition programs, as gift or pay, or from home-grown food. The low-income sample was divided about evenly between FSP participants and nonparticipants, between blacks and non-blacks, and by age of the household head (<35, 35-59, 60+). In addition, average household size was 2.63 adult male equivalent

adults, the vast majority of the households had a female head present (94%),⁵ and the sample was located largely in the South and in rural or nonmetropolitan areas.

Table 2 shows the OLS estimates for each nutrient equation. These findings show that the household availability of all nutrients is positively associated with both the food stamp benefit level and money income. The most striking result is that the estimated marginal impacts of the food stamp benefit consistently and significantly exceed those of cash income. While the estimates indicate positive and statistically significant effects on nutrient availability for both the food stamp benefit and cash income, the coefficient on the money income variable is always less than the coefficient on the food stamp benefit, indicating smaller marginal effects of money income on nutrient availability.

This point is examined in more detail in table 3. The first two columns show the "MPCs" (i.e., the marginal propensity to "consume" nutrients for the food stamp benefit and for cash income). The cash income MPCs are evaluated at the mean of cash income, and therefore represent the average MPC in the sample. As the table indicates, the MPCs for the food stamp benefit are much greater than the cash income MPCs. The ratio of the MPC for the food stamp benefit to the cash income MPC is never less than 3 and is as high as 7. This large difference is discussed in more detail below.

To judge the relative size of the estimated dietary effects, the third and fourth columns of table 3 show the marginal effects of the food stamp benefit and cash income as a percentage of the adult male RDA. The percentage effects of changes in weekly cash income are quite low, ranging from .3% to 1.2% of the adult male RDA, while the percentage effects of changes in the weekly food stamp benefit are higher, ranging from 1.8% to 3.9% of the adult male RDA. Interestingly, the percentage effects of changes in the food stamp benefit are similar in magnitude for most nutrients. That is, nutrient availability increases from between 1.8% and 3.9% of the RDA for a one-dollar increase in the food stamp benefit. These findings imply that increases in the weekly food stamp benefit are generally allocated proportionally among the nutrients examined.

The final two columns in table 3 show the estimated total availability of nutrients (as opposed to marginal changes) attributable to the

⁵ "Female head present" refers either to households with a female head only or to households with both a male and female head.

Notes: Absolute MPC is change in nutrient availability per ENU due to a one-dollar change in income per AME. Percentage MPC is absolute MPC divided by 1980 adult male RDA for the particular nutrient.

^a Defined as the level of nutrient availability attributed to food stamp benefits and cash income and calculated by multiplying the estimated coefficients by the average value of FSP benefits (for participants only) and cash income per AME.

food stamp benefit and cash income. These “total effects” are calculated by multiplying the estimated coefficients for the food stamp benefit, cash income, and cash income squared (all scaled by AME) by their respective average values for the benefit level and cash income for program participants. Except for vitamin C, phosphorous, and iron, the total availability of nutrients attributed to FSP benefits is either very close to or exceeds the availability of nutrients resulting from cash income.

Returning to table 2, the results indicate positive effects on nutrient availability of the subsidy value of school lunches and school breakfasts, although the latter is usually not statistically significant. The weekly value of home-grown and gift/pay food are also positively and significantly associated with nutrient availability and, in fact, the estimated coefficients for these two variables are significantly larger than the estimated coefficients for both the food stamp benefit and cash income variables. The number of AMEs in the household lowers nutrient availability per ENU. Nutrient patterns vary across region as well as by suburban and metropolitan residence, the two stratification variables used in the survey design.

Comparison of Results with Previous Findings

The OLS results indicate large and statistically significant differences between the estimated

coefficients of the food stamp benefit and cash income in the nutrient availability equations. The ratio of the MPC for the food stamp benefit to the MPC for cash income ranges from a low of 3 to a high of 7. The magnitude of these differences prompted us to examine more carefully the comparable results from previous studies to see if our findings are consistent with those in the literature.

Two studies were selected for comparison purposes, a study by Allen and Gadson and one by Basiotis et al. These two studies were selected because (a) both used data sources and had dietary outcome variables comparable to those used in our analysis, and (b) one had a model specification similar to that estimated in this study (Allen and Gadson) and the other a very different model specification (Basiotis et al.).⁶ Because these two studies used different model specifications, estimation procedures, and units of measurement (weekly versus daily measures of nutrient availability), their basic empirical results were adjusted to make their findings comparable. Because of the difference in model specification, the MPCs for the food stamp benefit could not be estimated from the Basiotis et al. study, but total impacts of the FSP could be.

The results from our study generally are sim-

⁶ In particular, the Basiotis et al. study included food expenditures as an independent variable in the nutrient availability equations and included the food stamp benefit as part of the household income variable.

ilar to those of Allen and Gadson. In particular, both studies report higher MPCs for the food stamp benefit than for cash income, and the magnitudes of the estimated coefficients are roughly the same across the two studies (with some exceptions). In addition, the estimated MPCs for cash income from the Basiotis et al. study are comparable in magnitude to those from this study.

However, estimates of the total effects of the FSP from this study generally are considerably larger than the comparable estimates from the Basiotis et al. analysis. This difference likely results from a model specification in that study in which the household income variable included the food stamp benefit, thus constraining the marginal effects of cash income and the food stamp benefit to be the same. Because the results of our study suggest differential effects of cash income and the food stamp benefit on nutrient availability, with larger MPCs for the food stamp benefit, the inclusion of the food stamp benefit in an overall household income measure leads to underestimates of the dietary effects of FSP benefits.

Selection Bias Models

The NFCS data used in the OLS regressions presented above include information on the food use of both FSP participants and FSP-eligible households not receiving FSP benefits (eligible nonparticipants). Because FSP participants are a self-selected group of low-income households, selection bias may exist if FSP households are high or low nutrient availability households to begin with, even before participation in the FSP and even if they had not participated in the FSP. The fact that eligible nonparticipants choose not to participate in the FSP suggests that they may differ systematically from participants in ways that may influence food consumption and, hence, nutrient availability. For example, if participating households are most in need of food assistance because of low initial food consumption, then OLS estimates of the effects of the food stamp benefit are downwardly biased. Conversely, participating households may have greater preferences for food than do eligible nonparticipants with similar household characteristics, leading to an upward bias in the OLS estimate of the effects of food stamps on nutrient availability.

Two types of selection bias are considered here, called Type A and Type B (Bjorklund and

Moffitt; and Ranney). The more common type of bias, Type A, arises when participants and nonparticipants in the FSP have different levels of food consumption, holding constant all other observed characteristics, even prior to participation in the FSP. In this type of selectivity, the problem arises because FSP participants and eligible nonparticipants differ, for whatever reason, in their initial level of food consumption. Type B selection bias arises if FSP participants and eligible nonparticipants have different marginal propensities to consume food (MPC) out of income. In this case, participants experience an increase in food consumption and nutrient availability that is different in magnitude than the increase that would be experienced by eligible nonparticipants if they were to participate.

The following set of equations represent Type A and Type B selection bias in model form:

$$(7) \quad N_{ki} = \alpha_k + \beta_{ki} (Y_i + \gamma_k B_i) X_i \phi_k + \epsilon_{ki}$$

$$(8) \quad P_i^* = Z_i \psi + \nu_i$$

$$(9) \quad P_i = 1 \text{ if } P_i^* \geq 0;$$

$$(10) \quad = 0 \text{ if } P_i^* < 0$$

$$\beta_{ki} = W_i \lambda_k + w_{ki},$$

where P_i^* is an index for the "propensity" to participate in the FSP, Z_i is a set of variables that affect that propensity, and P_i is a dummy variable equal to one if the household actually participates in the FSP and zero if not. Equations (8)–(9) represent a standard probit model for a dummy dependent variable. Included in Z_i is the potential food stamp benefit and cash income.⁷ If the error terms ϵ_{ki} and ν_i are correlated, Type A selection bias occurs. If they are positively correlated, OLS estimates of (7) yield upwardly biased estimates of the effects of food stamp benefits on nutrient availability; if they are negatively correlated, the opposite occurs.

This model has a single income variable, $Y + \gamma B$, where γ is the ratio of the MPC for the food stamp benefit to the MPC for cash income. The coefficient on this income variable, β_{ki} , is the MPC for income in general; it has a subscript "i" to allow for differences among households.

⁷ Specifically, the variables used as predictors of the likelihood of participating in the FSP are weekly cash income; potential food stamp benefit; race of the household head (1 = black, 0 = non-black); dummy variables for male head only or a female head only; dummy variables for the age, education, and employment status of the female household head (or male household head if there is no female household head); and a dummy variable for whether the household owns its home.

Thus, this model allows the MPC out of income to differ between FSP participants and eligible nonparticipants. As shown in equation (10), the MPC for income is assumed to be a function of a set of variables denoted by W and by an unobserved error term, w_i .⁸ Type B selection bias arises if the error terms w_i and v_i are correlated. If they are positively correlated, those households who have high MPCs even in the absence of the FSP (high w_i) are more likely to participate in the FSP.

Models with Type A selection bias and Type A and B selection bias were estimated using maximum likelihood estimation techniques (Maddala). That is, an FSP participation equation was estimated jointly with the nutrient

equations, using a maximum likelihood estimation technique and allowing the error terms of the participation and nutrient equations to be correlated.⁹ Given the complexity of selection bias models, the nutrient equations were estimated for only five of the nutrients: food energy, vitamin A, vitamin B₆, calcium, and iron. These five nutrients have the lowest average availability levels relative to the RDA and the lowest percentage meeting the RDA.

Table 4 shows the results of the important parameter estimates of the selection bias models for the five dietary components.¹⁰ Focusing first on the estimates for the Type A only selection bias model, the evidence for selection bias is weak. Of the five estimates of the cross-equa-

⁸ The set of variables assumed to influence the MPC for cash income are race, household size in adult-male-equivalent persons, number of guest meals eaten from household food supplies, dummy variables for the age (<35, 35-59, 60+) of the female household head, and dummy variables for whether the household lives in the South or in a suburban location.

⁹ With Type B selection bias, the individual-specific MPC is also assumed to be distributed normally and correlated with the error term in the nutrient equation.

tion correlation coefficients, only one is statistically significant (vitamin B₆), and that estimated correlation coefficient is not large. With the exception of calcium, the sign of the correlation coefficients is always negative, implying that FSP participants would have lower nutrient availability levels than nonparticipants in the absence of the FSP. As a result, for the four nutrients with negative cross-equation correlation estimates, the estimates of the MPCs for the food stamp benefit and the ratio of the food stamp benefit to cash-income MPC from the selection bias model exceed the OLS estimates. Despite the general lack of significance of the cross-correlation coefficients, the percentage change in the MPCs for the food stamp benefit from the OLS and selection bias models range from 14% for food energy to 26% for vitamin A.

Table 4 also presents the estimates from the Type A and Type B selection bias models. The correlation parameters are all statistically insignificant. The correlation parameters between the nutrient and FSP participation equations are, as before, generally negative (except calcium), but now are often smaller and less significant. The second type of correlation parameters are sometimes positive and sometimes negative, and are always low in statistical significance (much lower than those for Type A). As a result, the estimated MPCs for the food stamp benefit and for cash income from the selection bias models are quite similar to the OLS estimates. In addition, the OLS finding that the MPC for the food stamp benefit is significantly larger than the cash-income MPC persists with the Type A and B selection bias model.

Summary and Conclusions

The major finding of the empirical analysis is that the estimated dietary effects of changes in FSP benefits are considerably larger than those resulting from changes in cash income. While both the food stamp benefit and cash income have significant positive effects on nutrient availability, the estimated effects of changes in the food stamp benefit on nutrient levels consistently exceed the estimated effects of changes in cash income. The ratios of the MPC for the food stamp benefit to the cash-income MPC are consistently and significantly greater than one. The OLS estimates of these ratios range from 3 to 7, and the estimates from the selection bias models for selected nutrients range from roughly 2 to 7.

These large differences between the estimated effects of food stamp benefit levels and cash income on nutrient availability are generally contrary to the implications of theoretical household expenditure models (Southworth, Senauer and Young), and it is important to determine if these differences truly reflect the relative efficiency of coupon versus cash benefits in enhancing the quality of diets of participating households. To do this, two econometric models of selection bias were estimated for this study. Type A selection bias tests whether households with different initial levels of nutrient availability are more or less likely to be FSP participants; Type B selection bias tests whether the change in nutrient availability per dollar of cash income is greater or smaller for FSP participants relative to eligible nonparticipants. The results of the selection bias models show little evidence of either type of selection bias. Moreover, the estimated dietary effects of the food stamp benefit and cash income from the selection bias models are very similar to those from the basic model estimated by OLS regression. This absence of significant selection bias is an important finding; it suggests that underlying differences in either preferences for food or food demand functions between FSP participants and nonparticipants cannot account for the large and statistically significant differences between the effects of food stamps and cash income on household nutrient availability.

Demand for Food Fats and Oils: The Role of Demographic Variables and Government Donations

Brian W. Gould, Thomas L. Cox, and Federico Perali

A systems model of U.S. food fats and oils demand is estimated using quarterly time-series data for the period 1962–87. Demographic scaling is used to incorporate demographic variables and per capita government butter donations. In addition to price, income, and demographic demand elasticities, dietary fat intake elasticities are calculated for each of the demographic characteristics included in the study. All of the five own-price elasticities are statistically significant, as are fifteen of the twenty cross-price elasticities. Fourteen of the fifteen demographic elasticities are statistically significant.

Key words: AIDS, demand system, demographic scaling, nutrient elasticities.

Increased public concern with fat consumption, especially saturated fat and blood cholesterol levels, is evidenced by the 1988 report of the Surgeon General (U.S. Department of Health and Human Services). Over the 1962–85 period, total dietary fat consumption increased from 143 grams per day to 169 grams per day, an 18% increase. Over this same period, the per capita consumption of saturated fat remained relatively constant (58–60 grams/day), while polyunsaturated fat consumption increased from 22 to 33 grams per day (i.e., a 50% increase) and mono-unsaturated fat consumption increased from 59 to 68 grams per day (i.e., a 15% increase, Raper and Marston).

Red meats and food fats and oils are the two major sources of dietary fat. Both total and unsaturated fat intake from food fats and oils has increased relative to the fat obtained from red meat sources. This increase reflects the increased consumption of poultry and fish in place

of red meats, the increased consumption of food fats and oils, and the fat characteristics of these foods. Over the 1957–59 period, 40.9% and 54.5% of total dietary and polyunsaturated fat, respectively, were obtained from food fats and oils. These contributions increased to 47.2% and 68.2% by 1985 (Raper and Marston).

Figure 1 shows U.S. per capita disappearance of the five food fats and oils included in this study: butter, margarine, vegetable shortenings, salad and cooking oils, and lard. Steady increases in the consumption of vegetable shortenings, salad and cooking oils, lower consumption levels of animal-based fats and oils (i.e., butter and lard), and relatively constant margarine disappearance are shown.

The relative changes in the consumption of these food fats and oils raises questions about the causes. In this study a demand system is used to identify and measure the impacts of such factors. The specific objectives are threefold: (a) to incorporate a set of demographic variables into a demand systems model in a manner which avoids the shortcomings of previous efforts; (b) to examine how the per capita demand for food fats and oils is affected by a changing demographic profile (age, education, racial composition) and government butter donations; and (c) to examine how the dietary intake of total, saturated, and unsaturated fat has been affected by changes in the demographic profile of the U.S. population.

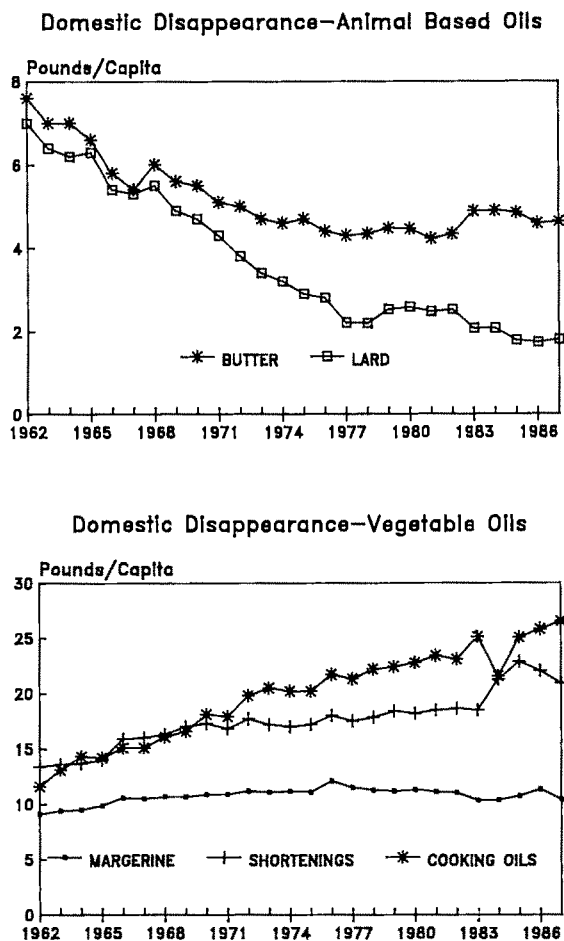

Figure 1. Per capita disappearance of food fats and oils, 1962–87

Description of the Demand System

Food choices are affected by demographic, social, and economic factors. In the model developed here, we hypothesize that the U.S. consumption of food fats and oils is determined by relative prices and tastes and preferences which, in turn, are reflected by socioeconomic variables. A set of demographic variables is incorporated into a demand system in which the demand for fats and oils is separable from the demand for other foods. That is, the consumer first decides on the level of fat and oils expenditure and then allocates these expenditures between the various food fats and oils sources based on relative prices and demographic characteristics.

Demographic characteristics can be modeled in several ways. The use of equivalence scales is one method; however, with this approach de-

mographic characteristics are virtually equivalent to changes in prices (Lewbel, p. 1). This restriction has been overcome through demographic translating, scaling, and Gorman procedures. In this study the demographic scaling procedure originally proposed by Barton is used so that the demographic variables can affect more than the "subsistence" or "necessary" parameters of the demand system (Pollak and Wales 1981).¹

Representing the original demand system as

$$(1) \quad D_i = D_i(P, S, M) \quad (i = 1, \dots, n),$$

where D_i is the per capita demand for the i th commodity, P is a vector of commodity prices, S is a vector of demographic characteristics, M is a given level of expenditure, and n is the number of commodities. Demographic scaling modifies this system as

$$(2) \quad \begin{aligned} D_i(P, S, M) &= \phi_i D_i^*(p_1 \phi_1, p_2 \phi_2, \dots, p_n \phi_n, M) \\ &= \phi_i D_i^*(p_1^*, p_2^*, \dots, p_n^*, M), \end{aligned}$$

where $p_i^* = p_i \phi_i$ are scaled prices and the ϕ_i 's are scaling parameters which are functions of the demographic variables, s_1, \dots, s_d :

$$(3) \quad \phi_i = \phi_i(s_1, \dots, s_d).$$

The scaling functions represent the number of commodity-specific "profile equivalents" (Pollak and Wales 1980). With respect to the demand for food fats and oils, preferences depend on the number of pounds per profile equivalent, i.e., pounds/ ϕ_i , and on the price per pound per profile equivalent, $p_i \phi_i$, where i is butter, margarine, etc., and ϕ_i is a profile of the consumer group, which is a function of demographic characteristics (Pollak and Wales 1981, pp. 1535–36).

Empirical analysis of the demand for food fats and oils using this model requires a functional form for (2) and (3). The almost ideal demand system (AIDS) model originally formulated by Deaton and Muellbauer is adopted because of the lack of a priori restrictions imposed on the substitution characteristics between commodities and the exact aggregation properties of this functional form (Deaton and Muellbauer). A

¹ Ray (1982) and Rossi apply the scaling function to household-level data. As noted by Rossi and by Deaton and Muellbauer, the scaling function can be interpreted as a measure of household size that takes into account age composition, other household characteristics, and economies of household size which can be used to deflate total expenditures to reflect a "needs corrected per capita level" (Deaton and Muellbauer, p. 314).

scaling function similar to the specification used by Ray (1982) and by Barnes and Gillingham is used to estimate equation (4):

$$(4) \quad \phi_i = \prod_r s_r^{\epsilon_{ir}},$$

where ϵ_{ir} are estimated coefficients.² Incorporating this scaling function into the AIDS model yields

$$(5) \quad w_i = \alpha_i + \sum_j \delta_{ij} \ln p_j^* + \beta_i \ln(M/P^*)$$

$$(i = 1, \dots, n),$$

where w_i is the share of the i th type of food fat and oil, and

$$(6) \quad \ln P^* = \alpha_0 + \sum_k \alpha_k \ln p_k^* + \frac{1}{2} \sum_k \sum_j \delta_{kj} \ln p_k^* \ln p_j^*.$$

With the incorporation of the scaling functions, the traditional homogeneity and adding up conditions still hold.³ In addition, equation (5) must be homogenous of degree zero in p_i^* as well as p_j . In order to maintain homogeneity with respect to p_i , (5) must be homogenous of degree zero with respect to the demographic variables. That is,

$$(7) \quad \sum_i \epsilon_{ir} = 0 \quad (r = 1, \dots, d).$$

Similar to previous studies that have incorporated demographic variables in demand systems, a linearized index (such as Stone's index using scaled prices) is assumed to provide an acceptable approximation to $\ln P^*$ (Capps, Tedford, and Havlicek). As such, equation (6) is approximated by

$$(8) \quad \ln P^* \approx \sum_k w_k \ln p_k^*.$$

In order to avoid simultaneity problems, we adopt

the Eales and Unnevehr approach where lagged budget shares are used in equation (8).⁴

In the AIDS model, expenditure, price, and demographic elasticities change over time as the share of each commodity changes. Differentiating equation (5), the expenditure (N_i), uncompensated price elasticities (Γ_{ij}), and compensated price elasticities (Γ_{ij}^*) can be calculated as

$$(9) \quad N_i = 1 + \beta_i / w_i,$$

$$(10) \quad \Gamma_{ij} = ((\delta_{ij} - \beta_i w_{j,t-1}) / w_i) - K_{ij},$$

$$(11) \quad \Gamma_{ij}^* = ((\delta_{ij} - \beta_i w_{j,t-1}) / w_i) - K_{ij} + w_j [1 + \beta_j / w_j],$$

where K_{ij} is equal to 1 if $i = j$, 0 otherwise. Similarly, differentiating (2) with respect to the r th demographic characteristic and converting to elasticity format (Pollak and Wales 1980), the elasticity of the demand for the i th good with respect to the r th demographic characteristic (E_{ir}) is a function of the uncompensated own- and cross-price elasticities (Γ_{ij}) and the elasticity of the i th goods scaling function with respect to the r th demographic characteristic, Ω_{ir} :

$$(12) \quad E_{ir} = \Omega_{ir} + \sum_j \Gamma_{ij} \Omega_{jr}.$$

Description of the Data

The demand for the five types of food fats and oils are analyzed using aggregate quarterly U.S. time-series data for 1962–87.⁵ Commercial butter disappearance data are obtained from various issues of *Dairy Situation* (USDA). Quarterly commercial disappearance for margarine, vegetable shortening, and salad and cooking oils are estimated from the following:

$$(13) \quad \text{COMMDIS}_t = \text{PROD}_t + \text{STOCK}_{t-1} + \text{IMPORT}_t - \text{EXPORT}_t - \text{STOCK}_t,$$

where *COMMDIS* is commercial disappearance, *PROD* represents production levels, *STOCK* are ending stock levels, *IMPORT* are imports, and *EXPORT* represents exports of the commodity. Various issues of *Current Industrial Reports: Fats and Oils Production, Consumption, and Stocks*

² As noted by an anonymous reviewer, the estimated scaling coefficients are assumed to remain constant over the study period. This assumption implies that, as more health information becomes available, the role of demographic characteristics in determining per capita consumption is unaffected. Future research could develop a time-varying scaling specification similar to the dynamic AIDS models developed by Moschini and Meilke and by Ray (1984).

³ The usual symmetry and homogeneity conditions on the AIDS share equations are adopted. We conducted log-likelihood ratio tests (Judge et al., p. 758) and could not reject these restrictions.

⁴ p^* is used in place of p in Stone's index because the underlying cost function is now dependent on p^* .

⁵ One problem with the use of this aggregate per capita disappearance data is that they encompass both intermediate and final commodity demand. Thus, the econometric results should be interpreted with caution.

are used to obtain monthly production and stocks (U.S. Department of Commerce). Annual import and export data are obtained from Putnam. For lard, various issues of the *CRB Commodity Yearbook* are used to obtain monthly commercial disappearance values (Buchman and Gaylann). Estimates of aggregate per capita disappearance values are obtained by dividing by quarterly population estimates obtained from published Department of Commerce sources.

Quarterly estimates of butter, margarine, and shortening prices are obtained from published BLS retail city average price series. Wholesale prices for salad and cooking oils and lard are converted to retail prices using data provided in various issues of the *Fats and Oils Situation* (USDA). These data, as well as those used for estimation, are available upon request from the authors.

The demographic variables are as follows: the median age of the population (*AGE*), the non-white proportion of the population (*NON-WHITE*), and the median years of schooling completed by those over twenty-five years of age (*SCHOOL*). These data are obtained from Bureau of the Census (*Current Population Reports* and *Statistical Abstract of the United States*). Quarterly values of the demographic variables are estimated by interpolating from the annual estimates of these variables. The variable *DO-NATE*, which represents per capita USDA donations of butter, is also used as an explanatory variable in each of the commodity-specific scaling functions. Estimates of quarterly government donations are obtained from *Dairy Situation* and other published USDA data (*CCC Milk Price Support and Related Activities*).⁶

Total expenditure for fats and oils (*EXPEND*) is the sum of the expenditures of each of the component commodities. Commodity-specific expenditure values and budget shares are obtained from the above estimates of prices and quantities.

Estimation Procedure

Given the adding-up characteristics of the AIDS share equations, only four equations in a five-

equation system are independent. Thus, the lard equation is dropped from the estimation, with the parameters of this equation estimated from the symmetry and homogeneity conditions. Because the model with demographic scaling is nonlinear in the parameters, an iterative seemingly unrelated regression procedure (SYSNLIN within the SAS system) is used for estimation. Price, expenditure, demographic, and donation elasticities are calculated from the estimated coefficients and corresponding share values. Approximate asymptotic standard errors are computed via the δ -method for the demographic elasticities because of the nonlinear nature of the elasticities (Rao).

The effects of seasonality in food fats and oils consumption are accounted for by several harmonic variables in each share equation.⁷ Following Doran and Quilkey, and Kinnucan and Fearon, these harmonic variables are calculated as

$$(14) \quad H_{1kt} = \cos(\lambda_k t) \quad (k = 1, 2) \\ (t = 1, \dots, T), \\ H_{2kt} = \sin(\lambda_k t) \quad (t = 1, \dots, T),$$

where

$$(15) \quad \lambda_k = 2\pi k/4 \quad (k = 1, 2).$$

With the incorporation of the scaling function [equation (4)] and the harmonic variables [equation (14)], the estimated AIDS share equations are

$$(16) \quad w_i = \alpha_i + \sum_j \delta_{ij} \left(\ln p_j + \sum_r \epsilon_r \ln s_r \right) \\ + \beta_i \left(\ln M - \left(\sum_j w_{j,t-1} \left(\ln p_j + \sum_r \epsilon_r \ln s_r \right) \right) \right) \\ + h_{i1} H_{11} + h_{i2} H_{21} + h_{i3} H_{12} \quad (i = 1, \dots, 5).$$

Estimated Coefficients and Elasticities

Table 1 presents the estimated demand system coefficients and associated asymptotic standard errors. All own-price coefficients are statistically significant at the 5% level except for the own price of lard. Six of the ten cross-price

⁶ Government donations are calculated as follows:

$$GD_t = GOVSTOCK_{t-1} - GOVSTOCK_t \\ + REMOVE_t - FDONATE_t,$$

where *GD* is government donations, *GOVSTOCK* is government ending stocks, *REMOVE* represents government net removals and *FDONATE* is foreign donation commitments.

⁷ A dummy variable specification was also evaluated to address seasonality in U.S. fats and oils consumption. Demand system parameters (price, conditional expenditure, and demographic effects) were quite robust across the dummy variable and harmonic specifications. Results for the harmonic specification are presented because it provided marginally superior explanatory power in terms of higher R^2 and log-likelihood values.

Source: Computed by authors.

Note: The model was estimated via iterative seemingly unrelated regression (ITSUR) using the SYSNLIN procedures of SAS. Asymptotic standard errors are presented in parentheses. The R²-statistic is computed as 1 - (sum of squared errors/corrected sum of squares of the actual dependent variable).

coefficients are also significant at this level, as is the butter and shortenings expenditure coefficients. Seven of the harmonic variable coefficients and nine of the estimated demographic coefficients are statistically significant at the 5% level.⁸

Table 2 shows the uncompensated price and expenditure elasticities evaluated at the means of the data. All of the own-price elasticities are statistically different from zero at the 5% level, as are fifteen of the twenty cross-price elasticities.⁹ In terms of the relationship between butter and margarine, the cross-price elasticity of the change in butter's price on margarine demand is statistically significant at the 5% level and is negative, indicating gross complementarity. Similar results are found by Goddard and Amuah, and by Cox for the Canadian fats and oils market. Similarly, margarine price has a statistically significant (gross) effect on butter (Marshallian) demand. All significant elasticities indicated gross complementarity except for lard and butter.

Table 3 provides a comparison of price and expenditure elasticities estimated here and those of Goddard and Amuah, Cox, and Huang. Goddard and Amuah, and Cox used Canadian quarterly data. To provide as close a comparison as possible, the elasticities obtained in the present study are reestimated using means of the independent variables over the 1973-86 period, the period over which Goddard and Amuah, and Cox estimated their models. The Canadian butter and margarine price and expenditure elasticities obtained by Goddard and Amuah, and by Cox are quite similar to those obtained in the current study. The results obtained by Huang are quite different; they may reflect the use of annual time-series data and a different time period for analysis.

From equation (12) we calculate the elasticity

⁸ The existence of fourth-order autocorrelation was examined by incorporating a variable representing residuals lagged four periods and estimated following the procedures proposed by Berndt and Savin. A log-likelihood ratio test of the null hypothesis that the autocorrelation coefficient is zero could not be rejected, indicating that fourth-order autocorrelation is not a problem (Judge et al., p. 758). With the harmonic variables, the values of the intercepts across quarters changed very little. For example, for butter the range was from .4004 in the third quarter to .4216 in the fourth quarter. The significance of the intercepts did not change appreciably across quarters.

⁹ Elasticities of substitution are estimated from the price elasticities presented in table 2. All of the own substitution elasticities are negative and significantly different from zero at the 5% level. Butter is a net substitute for margarine, vegetable shortenings, and cooking oils. Margarine is a net substitute for vegetable shortenings. None of the cross-substitution elasticities for lard are statistically significant.

Table 2. Uncompensated Price, Demographic, and Donation Elasticities Evaluated at the Sample Means (1962–87)

Dependent Variable	Price					Demographic Variables				
	Butter	Margarine	Short	Cooking	Lard	Expenditure	AGE	SCHOOL	NONWHITE	DONATE
Butter	-.662 (.057)	-.114 (.029)	-.128 (.045)	-.150 (.035)	.040 (.020)	1.094 (.040)	2.654 (.439)	-2.579 (.513)	-1.465 (.285)	-.003 (.002)
Margarine	-.130 (.037)	-.227 (.112)	-.171 (.082)	-.379 (.032)	-.100 (.022)	1.006 (.015)	-2.497 (.374)	-1.118 (.571)	1.008 (.221)	.001 (.001)
Shortening	-.079 (.048)	-.107 (.060)	-.421 (.096)	-.255 (.046)	-.030 (.022)	.891 (.049)	1.195 (.435)	2.346 (.524)	-.790 (.257)	.004 (.002)
Salad and cooking oils	-.083 (.027)	-.204 (.017)	-.210 (.035)	-.440 (.047)	-.045 (.014)	.982 (.019)	-1.751 (.260)	1.099 (.361)	1.642 (.126)	-.001 (.002)
Lard	-.146 (.069)	-.285 (.061)	-.164 (.095)	-.264 (.061)	-.277 (.112)	1.136 (.056)	1.574 (.748)	-1.812 (.851)	-2.667 (.583)	-.001 (.003)

Note: Because of the nonlinear nature of the elasticities, approximate asymptotic standard errors computed via the δ -method are provided in parenthesis.

of commodity demand with respect to changes in the three demographic characteristics (table 2). Fourteen of the fifteen demographic elasticities are statistically different from zero at the 5% level or better (i.e., all but *AGE/Lard*). *AGE*

has elastic and positive effects on butter, shortening, and lard demand and a negative impact on margarine and cooking oils. These results suggest the aging of the U.S. population increases (decreases) butter (margarine) demand.

¹ Huang delineated only three categories: butter, margarine, and other oils. The other oils category is presented in the shortening rows and columns. The elasticities estimated by Huang were obtained from an annual time-series model of the years 1953–81.

ceteris paribus. That is, older Americans have stronger preferences for butter relative to margarine, perhaps reflecting preferences acquired prior to the recent negative health concerns for cholesterol and saturated fat in the diet.¹⁰

The highly elastic, statistically significant and negative (positive) *SCHOOL* elasticity in the butter and lard (shortening) equations indicates that increases in the average U.S. level of education have reduced (increased) butter and lard (shortening and cooking oils) demand, *ceteris paribus*. These results are intuitively appealing under the hypothesis that higher education levels increase dietary/health awareness and concern. The result is a *ceteris paribus* substitution away from lard (and butter) to vegetable shortenings. The sign and magnitude of the *NON-WHITE* elasticities indicate that increases in the proportion of the nonwhite population have decreased (increased) the demand for butter, shortening, and lard (margarine and cooking oils), *ceteris paribus*.

The estimated coefficients of the government donations variable (*DONATE*) can be used to analyze the impacts of government butter donations on the demand for the five commodities in the study. While government butter donations are found to have small negative elasticity impacts on commercial disappearance of butter (-.003), these impacts are not statistically different from zero. The associated shortening elasticity is statistically significant and positive, although relatively small (table 2). One explanation of the magnitude and significance of the *DONATE/Shortening* elasticity (0.004) may be that the income gained from government donations is reallocated to the consumption of shortenings, a net substitute for butter (table 4). Hence, as butter prices decrease for the (relatively small) recipient portion of the population (i.e., it is free to those who receive the donations, but they are a small part of the total population), the complementary price effect of butter on shortenings (-.079, table 2) and the positive conditional expenditure elasticity (.891, table 2) combine to yield a small but statistically significant positive impact on shortening demand. However, given the conditional nature of these second-stage estimates, caution in their interpretation is advised.

¹⁰ As the U.S. population ages, the proportional impact of this older cohort increases. Hence, the *AGE* variable likely reflects cohort rather than pure age effects.

Table 4. Fat Composition of Food Fats and Oils

Type of Food	Fat Content (Grams/Pound)				
	Total Fat	Saturated Fat	Unsaturated Fat		
			Mono	Poly	Total
Butter	370	229 (62)	106 (29)	14 (4)	120 (33)
Margarine	366	72 (20)	163 (45)	115 (31)	278 (76)
Shortenings	454	114 (25)	202 (45)	118 (26)	320 (81)
Salad and cooking	454	68 (15)	195 (43)	171 (38)	366 (81)
Lard	454	178 (39)	205 (45)	51 (11)	256 (56)

Source: Guthrie, appendix A.

Note: The salad and cooking oils coefficients pertain to soybean oil (partially hydrogenated). The shortening coefficients pertain to vegetable shortenings. The figures in parenthesis correspond to the percent of total fat. They do not sum to 100 due to the inability to correctly identify and measure all fatty acids.

Changing Demographic Characteristics and Fat Consumption

Given the assumed separability of the consumption of food fats and oils from other commodities and following Pitt and Sahn, the elasticity response of the intake of the *m*th-type of dietary fat (i.e., total, saturated, and unsaturated fat) obtained from food fats and oils to a change in the *r*th demographic characteristic (*D_{mr}*) can be calculated:

$$(17) \quad D_{mr} = \left(\sum_i a_{mi} E_{ir} Q_i \right) / \left(\sum_i a_{mi} Q_i \right),$$

where *a_{mi}* is the quantity of the *m*th-type of dietary fat per unit of the *i*th-type of food, *E_{ir}* is the demographic quantity elasticity calculated via (12), and *Q_i* the predicted quantity of the *i*th food. The values of *a_{mi}* are obtained from table 4. The "fat intake" elasticities estimated via equation (17) are conditional because of the separability assumption, i.e., the fat intake associated with meat or other dairy products is not covered by this analysis.

Table 5 presents these elasticity estimates (with associated standard errors) for the mean values of the independent variables over the entire study period as well as point estimates for three quarters. Approximate standard errors obtained by the δ -method are also computed to facilitate interpretation. The predicted quantities for each type of fat or oil are obtained by using the estimated shares and actual prices for the three pe-

Table 5. Estimated Demographic Nutrient Elasticities, 1962-87 and Second Quarter 1967, 1977, and 1987

Variable	Type of Fat	1962-87	Second Quarter		
			1967	1977	1987
<i>AGE</i>					
	Total fat	-.355 (.068)	-.220 (.065)	-.224 (.074)	-.688 (.094)
	Saturated fat	.423 (.064)	.522 (.085)	.568 (.060)	.074 (.058)
	Total unsaturated fat	-.637 (.103)	-.495 (.094)	-.478 (.102)	-.920 (.121)
<i>SCHOOL</i>					
	Total fat	.461 (.078)	.403 (.084)	.474 (.082)	.580 (.120)
	Saturated fat	-.090 (.088)	-.127 (.120)	-.060 (.088)	.077 (.085)
	Total unsaturated fat	.661 (.108)	.601 (.103)	.646 (.107)	.734 (.148)
<i>NONWHITE</i>					
	Total fat	.170 (.039)	.001 (.038)	.091 (.042)	.482 (.054)
	Saturated fat	-.446 (.040)	-.593 (.049)	-.511 (.036)	-.172 (.036)
	Total unsaturated fat	.391 (.058)	.220 (.055)	.282 (.058)	.679 (.069)

Source: Computations by the authors.

Note: Because of the nonlinear nature of the elasticities, approximate asymptotic standard errors computed via the δ -method are provided in parenthesis. These elasticities are conditional on total expenditures for food fats and oils. These elasticities refer to the dietary intake of fat from these commodities. Hence, these elasticities do not include the fat intake from meat and other dairy products.

riods covered by this table. When viewing table 5, it should be noted that the coefficients for margarine, vegetable shortening, and salad and cooking oils presented in table 4 are aggregates of several different types of oils with varying fat compositions. The results may differ with a finer definition of food fats and oils.

The total fat elasticity for *AGE* is negative and statistically significant when evaluated over the 1962-87 period and for the three quarters evaluated. This implies that the aging of the U.S. population is associated with a statistically significant, *ceteris paribus* reduction of total fat intake from the commodities included in the model. In terms of the composition of this total fat consumption, a positive (negative) and statistically significant relationship between *AGE* and saturated (unsaturated) fat intake is obtained. These results primarily reflect the elastic impacts of *AGE* on butter (+), margarine (-), shortening (+), cooking oils (-), and lard (+) from table 3 and the associated fat compositions of these commodities (table 1).

Total fat consumption from the fat and oil commodities is positively affected by increased education (*SCHOOL* elasticities, table 5). These

results suggest that increasing education levels have increased consumption of unsaturated fats more than the associated decrease in saturated fats. These results are appealing under the hypothesis that, with higher education levels, the population has a greater ability to obtain information on, and understand the health impacts of, the consumption of certain types of fats. Conversely, one might expect better educated consumers to decrease their total fat intake (i.e., following dietary guidelines), not just saturated fat intake. The positive unsaturated fat *SCHOOL* elasticities may also reflect increased purchases of food away from home (*FAFH*) for those individuals with higher income levels. Much of these *FAFH* purchases occur in fast food establishments that use a large amount of vegetable-based fats.

The changing ethnic composition of the U.S. population appeared to have little impact on the intake of total fat except for the latter part of the 1980s. In contrast, the saturated fat elasticities were negative and statistically different from zero (5% level) for the late 1960s and 1970s. The unsaturated fat elasticities are positive and significant at all points evaluated.

Concluding Comments

This research analyzes the impacts of prices, fats and oils expenditures, seasonality, government butter donations, and demographic factors on quarterly U.S. fats and oils consumption over the 1962–87 period. The demand systems approach using an AIDS with demographic scaling specification performs quite well statistically and in terms of the implied elasticity results. In particular, the butter and margarine Marshallian price elasticities are similar (in signs and magnitudes) to the results of Goddard and Amuah, and Cox. The estimated impacts of the changing U.S. demographic profile [in particular, the aging of the population (*AGE*), increased average levels of schooling (*SCHOOL*), and increased proportion of the population that is nonwhite (*NON-WHITE*)] on fats and oils consumption are generally statistically significant and appear intuitively reasonable.

The nutrient/demographic elasticities indicate that the aging of the population (*AGE*) is associated with statistically significant decreases in total fat intake, but with increases in the amount of saturated fats and decreases in the amounts of unsaturated fats. One interpretation of these *AGE* results is that older consumers acquired strong (positive) preferences for butter (and vegetable shortening) prior to current concerns for cholesterol and saturated fat in the U.S. diet.

Increasing average education level (*SCHOOL*) is associated with statistically significant increases in total fat intake, but with negative (positive) impacts on the amount of saturated (unsaturated) fat from the commodities modeled. Increases in the proportion of the nonwhite population (*NONWHITE*) have little impact on the total intake of fats but to increase (decrease) the intake of unsaturated (saturated) fats. These results are conditional in so far as the fat consumption from sources other than those modeled here (e.g., meats and other dairy products) are not reflected in these results.

Government donations (*DONATE*) of butter have statistically insignificant and small negative impacts on commercial disappearance of butter. The results suggest that the potential reallocation of the "income transfer" generated by these donations is spent on shortenings; but, given the conditional (second stage) nature of the specification estimated, this result should be interpreted cautiously.

The inclusion of demographic information in the estimation of conditional demand systems

from aggregate disappearance data is strongly supported by this research. These procedures explicitly model changes in tastes and preferences associated with changes in the demographic profile, allow estimation of profile specific response parameters, and provide a natural basis for projecting demand based on demographic projections.

The success obtained here with respect to the use of demographic characteristics in demand systems estimation supports the continuation of research first initiated by Barton. Three areas of research that could extend the model developed here are (a) development of a model where the demographic coefficients are allowed to vary over time, (b) application of the model to household level cross-sectional data, and (c) extension of the Pollack and Wales (1981) demand systems model where the "appropriate" method (i.e., translating, scaling, Gorman) for incorporating demographic effects is parametrically tested when multiple demographic characteristics are included in the model.

Books Reviewed

Bowes, Michael D., and John V. Krutilla. *Multiple-Use Management: The Economics of Public Forestlands*. Washington DC: Resources for the Future, 1989, xxiii + 357 pp., \$40.00.

Bowes and Krutilla present theoretical models of multiple-use management for jointly produced services from public forestlands. These models are then used to analyze planning and harvesting decisions for several combinations of jointly produced services from selected U.S. national forests and to assess implications for federal budgeting of jointly produced services from national forests.

Bowes and Krutilla analyze an important policy issue. The 190 million acres in the U.S. National Forest System currently provide a large share of public recreational opportunities and approximately 30% of the domestic timber harvest. In addition to recreation and timber, these forests also provide other services including waterflow control, forage, minerals, and energy. The quantities of each service produced from the national forests are an enduring source of conflict. The management of U.S. national forests continues to be the subject of federal legislation, public planning, and legal actions. A several-fold increase in demand for both recreation and timber from the national forests since World War II has intensified use conflicts.

This book is timely. Historically, economic analysis has played a limited role in U.S. public forestland management. Most public forest decisions were made by foresters trained in the physical sciences. Many of these decisions may be characterized as supply responses to perceived demands. However, in response to federal legislation since 1960, the role of economics in U.S. national forest management has increased. While the opportunities for economic analysis have expanded, standard economic models of the single product, competitive firm are not directly applicable to public forestland management. The large relative size and characteristics of the public forests make analyses of jointly produced services, such as Baumol, Panzar, and Willig, inappropriate. The U.S. Forest Service is not a competitive firm. Competitive markets do not determine timber prices. For many types of recreation, value is difficult to assess, and exclusion is costly. A portion of the public forest is capable of jointly and simultaneously producing two or more services. To remedy the limitations of standard models, the authors explicitly incorporate characteristics of public land management and joint production.

Chapter 1 outlines the history of public forestland management and associated federal legislation in the United States. Chapter 2 describes services from U.S. national forests and trends in demands for those ser-

vices. Of note is the large relative increase in demand for recreation compared to timber from national forests since World War II and the mediocre quality of most national forestland for timber production.

Chapters 3 and 4 develop static and dynamic frameworks, respectively, for multiple-use management. Benefit and cost functions for jointly produced services are specified. In the dynamic model, amenity values are determined by the ages of several adjacent stands.

In chapters 5–10, the multiple-use management framework developed in chapters 1–4 is used to analyze selected planning, harvesting, and budgeting issues. The topics of analysis are the joint production of timber and water in the Upper Colorado River Basin (chap. 5), the effects of timber management on hunting quality in the Black Hills National Forest of South Dakota (chap. 6), the inclusion of both recreation and timber demands in the planning process for the White Mountain National Forest of New Hampshire and Maine (chap. 7), the incompatibility of providing recreation and producing minerals in the White Cloud Peaks of the Challis National Forest (chap. 8), the budget and appropriation process for unpriced resources services on U.S. national forests (chap. 9), and an evaluation of timber sales which do not cover costs on the Shoshone and Mt. Baker-Snoqualmie national forests (chap. 10).

Two important contributions of this book are the quality of the examples and the multiple stand determination of service values. The examples span a range of service combinations, are grounded in the current decision-making framework, and are well analyzed. The authors carefully exploit available data. The consistent use of willingness-to-pay and marginal, rather than total, changes is refreshing. Discussions for two controversial topics, FORPLAN, the linear programming planning model used by the U.S. Forest Service for forest plans, and below-cost timber sales, are balanced.

In most previous forestry models, the age of a single stand determines service values. All stands are harvested at the age that maximizes net present value of land. Here, the ages of more than one stand determine service values. This allows modeling of the joint effects of different aged stands in producing service values. With the consideration of multiple ages, optimal harvesting rules become both more credible and more complex. In contrast to the unique optimal harvest age of single stand models, no general harvest rule for every stand exists. That is, different stands may have different optimal harvest ages. For example, if users prefer a combination of younger and older stands, it may be optimal to harvest some stands more often and to harvest other stands less frequently or not at all.

This book is well written. Topics are well ordered, and transitions are smooth. The graphs are helpful. Throughout, the reader is treated to clear descriptions of standard forestry and resource economics topics. These topics include complements and substitutes, convex costs, the Faustmann Model, the Hartmann Model, maximum sustainable yield (MSY), even-flow timber restrictions, travel costs, and hedonic pricing.

This is an excellent book on a difficult and important policy issue. I expect it to become a supplemental text in many forestry economics, forest policy, and resource economics courses. The book will also interest those who desire an introduction to either the economics of multiple-use or public forestland management.

Reference

Baumol, W. J., J. C. Panzar, and R. D. Willig. *Contestable Markets and the Theory of Industry Structure*. New York: Harcourt Brace Jovanovich, 1982.

Braden, John B., and Stephen B. Lovejoy, eds. *Agriculture and Water Quality: International Perspective*. Boulder CO: Lynne Rienner Publishers, 1990, xii + 224 pp., \$25.

Braden and Lovejoy in the introductory comments of this book put the agricultural water quality problem in perspective with the statement: "Pollution from agriculture degrades more streams, more lakes, more ground-water aquifers and more coastal areas of the United States than pollution from any other source. And the United States is not alone" (p. 1). The broad perspective presented in the book is that nations are experiencing increasing difficulties, are unsure of directions to take, and wish to learn from others' experiences. Rather than attempting to deal with all aspects of agricultural water quality issues, the editors, working with a group entitled "Consortium for Agriculture, Resource and Environmental Policy Research," have focused on policy issues. An underlying thought driving the effort is that past policy approaches depending largely on educational programs and appeals for resource stewardship "have been overwhelmed by the capabilities of modern agricultural technologies and by rising public demand for environmental protection" (p. 1). The book is a compilation of ten papers prepared to deal with specific policy issues and cases and is arranged in three parts.

Part one, "Issues and Policy Options," is presented in three chapters. Libby and Boggess start with a chapter entitled, "Agriculture and Water Quality: Where Are We and Why?" which takes on the task of orienting the reader to the broad set of issues and considerations that make up the problem the other

authors deal with in more detail in subsequent chapters. They introduce many physical and technical factors and then focus attention on the policy aspects that will "demand attention by social scientists . . . in years to come" (p. 9). The two chapters following this overview focus on the two policy approaches: incentives and regulation. Segerson first presents the conceptual basis for incentive policies. She provides a thorough treatment of the economic logic underlying *ex ante* and *ex post* incentive mechanisms and includes discussion of a range of specific taxes, subsidies, and liability rules. Anderson et al. "focus on the current and potential use of regulation . . .," and in so doing "survey patterns of current agriculture regulations that have emerged around the world" (p. 63). This chapter also examines the economic theory underlying environmental regulation and compares the efficiency of incentive and regulatory approaches. Both chapters evaluate the strengths and weaknesses of their respective approaches for dealing with surface- and ground-water quality problems resulting from nutrients, pesticides, and soil erosion. All three chapters are thorough, and when taken together provide a useful view of the economic concepts underlying both incentive and regulatory approaches.

Part two, "Policy Applications," consists of five chapters that have as their purpose the introduction of real-world issues and experiences. Kumm describes and analyzes incentive policies, i.e., fertilizer taxes, afforestation subsidies, and intensive extension programs, that have been used in Sweden to reduce nutrient pollution. Denmark is also attempting to reduce nutrient loading from animal wastes and fertilizers and is investigating policies to reduce pesticide use. Dubgaard discusses the proposed tax policies and reports on research by the Danish Institute of Agricultural Economics. In both the Swedish and Danish cases, it was not possible to point to conclusive evidence as to the effectiveness of the various policy approaches.

Reichelderfer, in reviewing U.S. programs, points out that "historically, direct and indirect positive incentives have been the most popular instruments for agricultural (including agroenvironmental) policy implementation" (p. 131). Most federal programs have focused on erosion control, but in recent times more specific surface- and ground-water quality issues are being raised. An important conclusion is "that new incentive policies and programs need to be designed in anticipation of shifting social, economic, and political conditions—not tied to the short-term conditions existing at the time of policy formulation" (p. 142). Helfand and Archibald, in a chapter entitled "California's Proposition 65: A New Regulatory Trend," give insight into these rapidly changing conditions occurring at the state level. Their discussion illustrates the measures voters are willing to take to force policy makers to recognize their environmental concerns.

The last case, by Musgrave, illustrates that often

a formal relationship between a number of jurisdictions is needed to create the basis for dealing with a water quality problem. Australian federal and four state governments had to form a regional compact to deal with the Murray-Darling Basin water problem. The agreement "provides each state with a clear statement of its obligations and rights . . ." but leaves the "states free to pursue their own programs within the resulting framework" (p. 176). Potential for use of economic incentives is seen.

Up to this point the first eight chapters of the book have presented issues and cases from a "multi-national perspective." Only in part three, "Environmental Policies and Agricultural Competitiveness," consisting of two chapters, are international issues and perspectives raised. Runge points up the emerging issue of environmental regulation and protectionism. Recognizing the potential of non-tariff barriers, he calls for GATT negotiations to broaden policy considerations and "prevent protectionism from masquerading as health and safety standards" (p. 195). Young, in the last chapter, further considers trading arrangements, intensity of resource use, and environmental quality, and is the only author to address environmental concerns in less developed countries. He recommends the OECD "Polluter-Pays Principle" as a starting point for international discussions on agricultural trade and environment.

As one would suppose, the book raises many more questions than it answers. But as is often the case, this is the way to make progress. The book provides a good starting point for understanding the major policy issues related to agriculture and water quality and points the way for policy research.

Clyde F. Kiker
University of Florida

Cohn, Theodore H. *The International Politics of Agricultural Trade: Canadian-American Relations in a Global Agricultural Context*. Vancouver, B.C.: The University of British Columbia, 1990, x + 267 pp., \$36.95.

Billed as the first major examination of Canadian-American agricultural trading relations from a political perspective, this volume traces the evolution of U.S.-Canadian trade relations from the 1950s to the 1980s and examines the bilateral and multilateral forces that resulted in the Free Trade Agreement (FTA) that went into effect on 1 January 1989. For American readers, the more interesting aspects may be Cohn's rendition of bilateral trade history with its Canadian perspective; for Canadian readers, the interest may lie more in the forces that shaped the highly controversial FTA. For all readers, the analysis of forces shaping agricultural trade and its growing international importance will be of interest.

Of special interest to classroom teachers will be chapter 3 on "The Organizational Setting" of agricultural trade. After describing the evolution of the

General Agreement on Tariffs and Trade (GATT), Cohn outlines a multiplicity of other international organizations that influence the structure and conduct of agricultural trade. Interwoven into this discussion are the special waivers, such as section 22, that the United States has enjoyed *vis-à-vis* agriculture and the GATT. This is useful information in light of its significance in the recent round of trade negotiations. Cohn also summarizes the agricultural components of the Kennedy and Tokyo Rounds that tried, but largely failed, to make progress on agricultural trade liberalization.

Of interest to the economic academician will be chapter 4, on "International Pricing Arrangements." This chapter outlines the many attempts to establish duopoly and oligopoly pricing in world grain markets. Included are the lesser-known efforts by the United States and Canada to coordinate grain-pricing policies during and after World War II. It was a surprise to this reader, for example, to learn that "The CWB (Canadian Wheat Board) was then (1943) invited to occupy an office in the U.S. Department of Agriculture Building" (p. 67) in Washington. This presence continued until Dwight D. Eisenhower became president in 1953, at which time "the advantages of these close contacts became less evident to his administration" (p. 67).

Cohn then reviews the extended periods of low grain prices that followed, the many unsuccessful attempts to stabilize markets at higher levels and traces out more recent experiences with grain embargoes, export subsidies, and the U.S. plan for world agricultural trade reform. The reactions of political leaders to these efforts makes engaging reading.

Less engaging to American readers will be chapter 5 on "American Surplus Disposal Measures." Here Cohn describes the long series of diplomatic efforts by Canada to alter U.S. behavior regarding grain disposed of outside commercial channels. As Cohn points out, "Canada was a persistent and harsh critic of American tied sales provisions in PL 480 agreements, maintaining that they interfered with the commercial trade of other exporters. The United States, on the other hand, felt that tied sales were an essential component of its food aid and trade policies" (p. 92).

Cohn also describes U.S. efforts to use barter as a means of disposing of surplus commodities, which Canada also opposed, and concludes that "American tied sales and barter were prime illustrations of the vast differences in U.S. and Canadian economic size and capabilities" (p. 110). This theme, that Canada is small in economic size compared to the United States, and by implication that Canada should receive special trade treatment, is echoed in a number of places in the volume. It is not a view that is widely held in Washington agricultural circles.

Of more interest to American readers will be chapter 6, which describes "Canadian and U.S. Agricultural Export Credits." In this case, Canada is portrayed as actively involved in providing trade credit

to other countries. Cohn notes, "the provision of credit normally does not require massive amounts of economic resources. Canada was therefore able to compete with the United States in the export credit sales area, and both countries at various times took the lead in adopting innovative practices" (p. 111). This chapter provides an enlightening description of the role that trade credit has played in expanding world agricultural trade.

The final chapter deals with the issue of "Agricultural Trade Barriers." In a sagacious statement, Cohn observes that "Canadian-American agricultural trade has alternated historically between cycles of protectionism and liberalization" (p. 139). This is a useful reminder, especially for younger readers. It is quite easy to become so immersed in the current minutia of trade policy that one loses sight of how it waxes and wanes over time. We should keep in mind that only in the post-World War II period has trade liberalization been in the ascendancy. Prior to that, protectionism was the order of the day. That is why volumes like this are so valuable. They remind us that we should not take trade liberalization for granted. Over the course of history, free markets and free trade are the exception rather than the norm. Like liberty, the price of free markets and free trade is eternal vigilance. And, like an appreciation of liberty, this starts in the home and classroom.

In this instance, Cohn has provided us with the information to stay vigilant. His volume should be of interest to classrooms and boardrooms that deal with international agricultural trade and especially those with a focus on U.S.-Canadian trade relations. He provides us with an excellent historical review and description of the political and economic forces that have brought the United States and Canada into a closer trading relationship. Based on the reminders in this volume, however, we should not take that relationship for granted. There are forces working to limit it. We can only hope they weaken over time. Perhaps this volume may help achieve that goal.

Committee on Agriculture

Fuguitt, Glenn V., David L. Brown, and Calvin L. Beale. *Rural and Small Town America*. New York: Russell Sage Foundation, 1989, xxvii + 471 pp., \$55.00.

This volume is one in a continuing series of monographs prepared for the National Committee for Research on the 1980 Census. Written by three noted experts on the demography of rural America, this book provides a thorough and well-documented statistical portrait of rural and small town America circa 1980. Although based primarily upon 1980 and earlier census data, the volume also draws upon national surveys and population estimates for information on the post-1980 period. Aimed at interested public officials

and nonprofessionals, as well as professional social scientists, the book is clearly written and procedures used are carefully described.

The thirteen chapters that constitute the book may be divided roughly into three main categories: (a) population growth and distribution, (b) demographic and socioeconomic characteristics, and (c) economic activities of the population. Chapter 1 describes the organization of the volume and contains a useful discussion of what is meant by rural and small town America. The authors note that their focus is on "(1) the rural population, metropolitan or nonmetropolitan; and (2) the urban nonmetropolitan population" (p. 6). Changes in the census definitions of rural and urban and metropolitan and nonmetropolitan complicate comparisons over time, as does the movement of areas into or out of these classifications. The authors are careful to note and/or adjust for the impact of these changes on their results.

Chapters 2 and 3 describe trends in population distribution and document the pervasive population deconcentration that occurred in the United States during the 1970s. The widely noted "population turnaround," in which nonmetropolitan areas grew more rapidly than metropolitan areas, is analyzed as part of a much larger movement toward population deconcentration that took place at several territorially based levels. The authors note: "This included population decline in the nation's largest cities, a continuing pattern of metropolitan suburbanization, more rapid growth in smaller than larger Metropolitan Statistical Areas, population redistribution away from the densely settled North, and a reversal in growth patterns between metropolitan and nonmetropolitan areas" (p. 100). The reversal of the turnaround in the post-1980 period is also described and major regional differentials in metro-nonmetro growth are documented. What emerges from this analysis is a picture of substantial diversity in growth patterns by major regional and residential categories.

Chapters dealing with demographic and socioeconomic characteristics present a detailed analysis of compositional differences across residential settings. Many of these findings will confirm the reader's expectations with regard to rural-urban and metro-nonmetro populations. However, some findings challenge beliefs about rural America. For example, in spite of higher rural fertility throughout the nation's history, the "oldest population is disproportionately located in nonmetropolitan areas . . ." (p. 137). This is not only the outcome of the selective outmigration of young adults from nonmetro to metro areas, but increasingly since the 1960s, the selective immigration of the elderly to nonmetro locations. Similarly, the stereotypical picture of Hispanic farm workers is belied by the finding that 90% of Hispanics were urban by 1980, making them one of the most urban ethnic groups in the nation. Perhaps less surprising, but no less important, is the continuing significance of residence for household composition and structure. "Rural areas continue to be characterized by more

traditional household structures, in terms of both family living arrangements and life course composition of householders" (p. 183).

The continuing disadvantage of rural and nonmetropolitan residence is ably documented in the chapters dealing with the economic activities and income of the population. Excellent chapters on the labor force and employment, industrial structure, the population associated with farming, and income and poverty reveal the expected patterns. For example, the percentage living in poverty in nonmetropolitan areas in 1986 was 18.1, compared to the metropolitan rate of 12.3. Similar differences favoring metropolitan residents are found for a variety of employment and income measures.

Rural and Small Town America represents an important addition to our understanding of the significance of residence for America's social and economic structure. No reader interested in population distribution or the hierarchy of urban places can afford to ignore this volume. Given the wide range of topics covered and the uniform quality of the coverage, the volume will be of particular interest to agricultural economists interested in rural development, rural sociologists, demographers, and geographers, among others. Two minor cavils distract the reader from what is a valuable contribution to the literature. Chapter 12, on the characteristics of cities, towns, and rural areas, appears curiously inconsistent with the organization of the book. The customary delay in publishing census monographs is likewise discouraging. However, neither of these quibbles seriously diminishes the value of this work which is likely to become the standard reference in the area.

C. Shannon Stokes
Pennsylvania State University

James, W. E., S. Naya, and G. M. Meier. *Asian Development: Economic Success and Policy Lessons*. Madison: University of Wisconsin Press, 1989, 281 pp., \$37.50, \$13.50 paper.

This book reviews and appraises the unprecedented economic development record of countries of Asia. The authors' note states the book "focuses on the extraordinary performance of the Asian newly industrializing countries (NICs) (Hong Kong, Korea, Singapore, and Taiwan), the four resource-based countries of the Association of Southeast Asian Nations (ASEAN-4—Indonesia, Malaysia, The Philippines, and Thailand), and the low-income countries of South Asia (Bangladesh, Burma, India, Nepal, Pakistan and Sri Lanka)" (p. xv).

The book is divided into seven chapters, the first of which provides a comparative overview of each of the countries in the three groupings listed above. The subsequent chapters discuss industrialization and trade policy, savings and development, financial flows and debt, agriculture, human resource development and, finally, policy lessons and prospects.

The major focus of the book is that "a given country's course of development appears not to have been limited by its 'initial conditions,' but to have been determined by the quality of its economic policies" (p. 21). Each of the respective chapters illustrates in detail this concept and provides an empirical data base to support the thesis that what matters most are appropriate policies.

One might surmise this conclusion, given that the study originated from research initiated while the authors were at the Economic Office of the Asian Development Bank (p. xvi). The book is expected to serve a wide audience of economists and noneconomists. It avoids the use of mathematical formulas and keeps technical and theoretical issues at an easily understood level, even for the noneconomist. In this regard, it should be useful to students in business and the social sciences, particularly those concerned with Asian and Pacific areas. Nevertheless, the economic management lessons detailed for the respective countries are broadly applicable in other developing countries.

Among the book's strengths are the numerous, well-organized tables and graphs that increase the book's usefulness to the researcher, student, or government official concerned with understanding and tailoring well-designed investment projects. The comprehensive and current bibliographic references plus the chapter notes are of great value to reacquire agricultural economists with the need to conduct agricultural analysis and policy applications within the broader macroeconomic framework. Chapter 3, which thoroughly explores the role of domestic savings and financial development, provides a classic primer on the need to follow nonrepressive financial policy if a country is to grow rapidly.

One might quarrel with a few minor points, i.e., on page 3 it is stated: "But a quarter century of spectacular economic growth in the Asia-Pacific region has shifted the center of the world economy from the Atlantic to the Pacific." This may be occurring, but as yet the shift is still underway and certainly has yet to be achieved.

On balance, this is an excellent book and valuable for the insights it provides for understanding the differentials of growth among Asian developing countries. It should be considered required reading for all developing country decision makers. While the political and social context of the Asian countries is in several respects obviously different from the situation found in Latin America and Africa, the fiscal, monetary, financial, and trade policies pursued so successfully in the newly industrializing countries represent universal economic principles which, if astutely developed and systematically followed, incorporate the basis for a dynamic evolution to self-sustaining economic growth and wealth.

Alfred Thieme, Jr.
Inter-American Development Bank

Moore, Richard H. *Japanese Agriculture, Patterns of Rural Development*. Boulder: Westview Press, 1990, 337 pp., \$35.00.

The core of this book, and its most valuable contribution, is an intensive case study of Nakada township in the rice-growing Tohoku region of northeast Honshu. Its focus is that of an ethnographer who is sensitive to the persistence of age-old value systems and social structures in a rural community and its (so far successful) effort to survive in a rapidly changing economic environment. The author leads us through the history of the township and one of its villages; its customs and beliefs; the pattern of land ownership and tenancy and the influence of irrigation; the (limited) effects of land reform and countervailing government efforts to promote productive efficiency through land consolidation and leasing; the advent of mechanization, freeing labor for off-farm employment; the survival of both full-time and part-time farms under the protective umbrella of high price supports and subsidies; and the role of the agricultural cooperatives in protecting farmers and managing change.

Throughout the book, microeconomic findings based on the author's field work are intermingled with nation-wide events and policies. A final chapter, added at the urging of the editor, deals with current governmental attempts to accelerate structural changes in order to increase the economic efficiency of the agricultural sector, to reduce support costs, and to open the market to international competition.

It is evident throughout that the author shares the traditional rural values and takes a dim view of any attempt to promote or even facilitate structural change in agriculture. To be sure, he does applaud the growth of off-farm employment, which he rightly credits with helping to preserve the rural communities (although he fears that this escape hatch may be gradually closed by a decline in industrial subcontracting). But he does not accept the economists' prescription that the future of Japanese agriculture lies in larger-scale farming employing fewer farmers and a shift away from rice to livestock products, vegetables, and fruits for which consumer demand is growing and in which Japan is, or can become, internationally competitive.

The author is not comfortable with economic analysis. In any event, he makes clear that his priorities are different. "The focus needs to be redirected from the narrow logic of free trade rules or political convenience to the nutritive value of the Japanese diet, the ecology of food, and its cultural significance" (p. 1). "The central components of any solution to the farm dilemma in Japan must involve the cultural right of the members of the farm household to perpetuate their corporate body through succession, inheritance of land, and ancestor worship" (p. 272). He sees "the main problems encountered by rural society" in "the bride shortage and aging rural population" and in "growing disparities . . . in job security" (pp. 272-73). He marshals environmental and dietary arguments and the cultural symbolism attached to rice in defense of the status quo. On the whole, the book is

more helpful in understanding the persistence of a highly fragmented, rice-based agricultural structure in Japan (including the reluctance of farmers to sell, or even lease land) than in providing a guide to its adaptation to changing economic conditions.

Although the book contains much interesting information, frequent digressions and repetitions make it difficult to read. The presentation could have been improved by more rigorous editing. An overview chapter would have helped to give the nonexpert reader a feel for the broad historical sweep of the evolution of Japanese agriculture before immersing him into specific aspects as seen from the grassroots.

Fred H. Sanderson

*National Center for Food and Agricultural Policy,
Resources for the Future*

Pearce, D. W., and R. K. Turner. *Economics of Natural Resources and the Environment*. Baltimore MD: Johns Hopkins University Press, 1990, 378 pp., \$42.50, \$19.50 paper.

Public interest in environmental matters has enjoyed a recent resurgence. It will not be surprising to find that enrollments in undergraduate courses in environmental and natural resource economics will rise with this resurgence. It is to this audience that Pearce and Turner offer their volume. It is a difficult audience to satisfy given that it has a very diverse range of disciplinary backgrounds. Some potential readers will be already skilled in economic principles and analysis. Others will have backgrounds more in the physical sciences.

Acknowledging this difficulty, Pearce and Turner have attempted to provide a text that strikes a balance. They seek to satisfy the economist with sufficient mainstream analysis, while not deterring the ecologist from pursuing the subject. They seek to offer an intellectual challenge to the economist while giving enough practical relevance to maintain the noneconomist's interest.

The approach used in striking this balance is to follow a distinct pattern of analysis. First, the authors go to some length to begin their various analyses using widely understood statements of environmental issues. They then proceed to "translate" these generalized statements into specific economic formulations of the issues. Once so formulated, relatively standard economic analysis is applied.

The results of the approach will not please all. A good example of problems faced by the approach is the treatment of that currently omnipresent concept, sustainable resource use. The translation offered by Pearce and Turner of this infrequently defined concept is useful in that it helps both economists and noneconomists to understand exactly what is being considered. However the economist's translation in terms of optimal rates of depletion of the natural capital stock will no doubt be disturbing for environmentalists. Similarly, the conclusion reached by Pearce

and Turner that sustainability involves the maintenance of the currently available stock of natural capital will be disturbing to many economists. The authors propose a "sustainability requirement" (p. 225), whereby any reductions to the natural capital stock would need to be compensated for by additions to that stock achieved by other projects within the portfolio of decisions being made. These augmenting projects "would not be required to pass any test relating costs to benefits" (p. 225). While the ardent environmentalist may find this proposition appealing, most economists will see it as a prescription for the creation of a poorer society, less able to afford environmental protection.

A second problem created by the approach relates to the breadth of material that is covered. Words devoted to the balancing of environmental and economic approaches are words not used to discuss other important issues. For instance, scant regard is paid to the office choice theory explanation of the popularity of the strongly interventionist approach to pollution control. A consideration of the importance of the lobbying of special interest groups and the roles bureaucrats and politicians versus the impotency of the individual voter would have added a useful dimension. Similarly, there is little attention given to institutional arrangements that have caused the breakdown of the property rights approach to the resource allocation process.

Another notable omission is a systematic treatment of benefit-cost analysis. As the book progresses, more and more reference is made to the measurement and weighing up of benefits and costs, yet nowhere are the basic framework and fundamental assumptions of benefit-cost analysis established. To the uninitiated this could be confusing.

However, there are also distinct advantages of the approach used. Global pollution problems and policies are often overlooked by texts, but this volume devotes a complete chapter to their consideration. Likewise, the volume extends the analysis to cover centrally planned and developing countries. With such interest in all of these issues, the book's breadth of coverage is welcome.

The authors' style is clear and concise, particularly in the analytical sections of the book. The clarity is aided by the use of diagrams that are uncluttered and simple to follow. The conciseness is aided by the book's structure: chapters tend to be short and address very specific topics, so that ideas and concepts are tightly packaged. The subdivision of chapters shows to full advantage the organization of the underlying argument. These features will enhance the ability of students to assimilate the material covered by the book. Its limited use of mathematics will delight some and frustrate others.

The volume recognizes that noneconomists are not only concerned about the environment but are also interested in finding out what and how economists think about environmental issues. Its analysis is not condescending to noneconomist readers in that it is not overly pedagogical. Yet it has enough footholds

back to environmental basics to make the nonspecialist feel comfortable. For the economist, there is sufficient analytical strength to provide a stimulating challenge. Part of that challenge will be coming to terms with the views of physical scientists and seeking solutions to the environmental problems they pose.

Jeff W. Bennett

University of New South Wales, Australia

Rawski, Thomas G. *Economic Growth in Prewar China*. Berkeley: University of California Press, xxxiii + 448 pp, \$48.00.

This book is required reading for those interested in China's economic development, be they economists, historians, researchers, teachers, or students. Rawski has set out to expose conventional beliefs about China's modern economic history to the harsh light of empirical evidence. The evidence he presents is likely to change, or at least raise serious questions about, those beliefs.

Rawski challenges the view that China's economy was in a state of stagnation during the prewar period. He presents new estimates of growth rates for China's GDP between 1914–18 and 1931–36. These estimates imply per capita GDP growth at rates of about 1% a year, or possibly higher. Such growth exceeds previous estimates by K. C. Yeh and Dwight Perkins of less than 0.5% a year, and it resembles growth achieved by Japan during 1897–31, a period of accelerating growth. Rawski's estimates imply that the economy was not stagnating: real per capita income rose over 20% between 1914–18 and the 1930s.

A wide range of related evidence is used to back up these estimates. Data are most abundant for, and the book focuses on, the modern sector. Separate chapters are devoted to manufacturing, banking and the monetary system, and transport and communications. For each of these sectors, Rawski weaves together data from diverse primary and secondary sources. The picture that emerges is one of dynamism, where modern firms grew and spread regionally and where modern and local institutions frequently achieved a symbiotic relationship. This picture contrasts with the conventional view that the modern sector was limited in influence, did not penetrate beyond a few major urban centers, and grew at the expense of traditional industries.

A chapter on investment examines whether the investment levels were high enough to initiate a long-term growth process. W. Arthur Lewis and Walt Rostow have suggested that "take-off" involves a transition from low investment at or below 5% of gross national product (GNP) to high investment at 10% or more of GNP. Earlier work on China by K. C. Yeh shows gross fixed investment in the 1930s at only 5% of national product. In contrast, Rawski estimates that by that time fixed investment had risen to about 10% of GDP. If correct, these findings contradict beliefs that rates of return on investment were low, that uncertainty and instability prevented investment, and that

for cultural or social reasons China's elites were unwilling to invest.

The credibility of Rawski's arguments rests on the evidence. Information is most abundant and his analysis strongest for the modern sectors. The modern sectors, however, accounted for only 10%–15% of national product. Conclusions about the overall economy, then, require estimates for growth and investment in traditional sectors, especially agriculture. Unfortunately, systematic, nationwide data for output and investment in agriculture do not exist. Rawski therefore uses indirect evidence. Data showing rising cotton cloth consumption and rising wages of unskilled labor from rural areas suggest that incomes and living standards were increasing in rural China. Under certain assumptions, these data imply rising farm output.

Despite the careful discussion of these indirect data, Rawski's conclusions about trends in agriculture, and thus for the economy as a whole, are suggestive rather than definitive. Nevertheless, his study brings important new evidence to bear on the subject. Moreover, if one is uncomfortable with Rawski's estimates for agricultural growth, one must be equally (if not more) uncomfortable with previous estimates. Earlier studies face the same data problems and rely on equally strong assumptions.

I should add that my favorite chapter is the first one, in which Rawski demolishes the view that the prewar Chinese economy was ravaged by militarism and a corrupt, extractive government. Militarism and the government may very well have disrupted the economy in particular regions at particular times. Yet, data show that the numbers of troops, casualties, and military outlays were small relative to the population and economy as a whole. Similarly, data for the 1930s show central government expenditures averaged less than 3% of GDP, and Rawski estimates total government spending (all levels) at between 4.7% and 7.2% of GDP. The government's ability to raise taxes was apparently weak, and so its ability to "extract" resources from the economy was probably limited.

By insisting on systematic evidence as the basis of our views, Rawski has raised the level of debate about China's prewar development. Those who disagree with Rawski's conclusions will either have to refute the data he presents, provide alternative evidence, or challenge his interpretations of the data. Regardless of whether they agree or disagree, readers will find this book a gold mine of primary source references and materials, and a very stimulating work.

Reitsma, H. A., and J. M. G. Kleinpenning. *The Third World in Perspective*, 2nd ed. The Netherlands: Van Gorcum, Assen/Maastricht, 1989, xxii + 435 pp., price unknown.

This book was written by two geographers, and it covers the politics, the economics, the sociology, and the legal aspects of development and underdevelop-

ment in addition to geographical aspects. A hint at the breadth of coverage is given by a brief synopsis on the outside back cover of the book. Issues to be described and explained include low productivity, food shortages, poverty, infrastructural deficiencies, underutilization of human and natural resources, population explosion, unemployment, rural-to-urban migration, unbalanced spatial structures, shantytowns, oversized informal sector, inequality, internal colonialism, and corruption. It is designed as an undergraduate textbook but may also serve as supplementary reading for graduate courses. It is rich in illustration—maps, graphs, and photos.

The book is organized into five parts, including twenty chapters and an epilogue. Part one looks at changing perceptions of the third world's underdevelopment beginning with the decade 1945–55 and ending with the decade 1975–85. Part two treats the rural-agricultural scene, while part three covers the urban-industrial scene. Part four's three chapters cover various theories of development and underdevelopment including critiques—especially of the theories of imperialism and dependency. Finally, part five is devoted to a fairly detailed analysis of four country case studies: Ethiopia, India, Cuba, and Taiwan.

This is an excellent book. It is well written and easily comprehended. In their critiques of some theories of development and underdevelopment, the authors make every effort to present a balanced view. They conclude that during the 1960s and 1970s colonialism was overemphasized as a major negative influence. Reitsma and Kleinpenning try to balance this view by giving more attention to the internal factors of the physical and cultural environment operating throughout the centuries. The case studies were selected to provide some comparative testing of a number of the theoretical concepts of development and underdevelopment. In the epilogue, the authors provide their rationale for the countries selected for their case studies, and they present some interesting contrasts with respect to physical and cultural environmental factors, the role of indigenous elites, colonialism, and others.

With respect to colonialism, they conclude as follows: "With the exception of five years of Italian occupation, Ethiopia never was a colonial possession. Today it is one of the world's poorest countries. After fifty years of colonial rule by the Japanese, Taiwan is presently well on its way to becoming a prosperous and developed country. Both Cuba and India were colonial dependencies for a very long period of time, but present living conditions of the 'average' inhabitant are far better in the former than in the latter country" (p. 393).

In chapter 14, "Causes of Underdevelopment: An Overview of Theories" (pp. 211–38), the authors draw heavily on the views of two European geographers, Hans Bobek from Austria and Yves Lacoste from France. Both of these writers have serious reservations concerning the one-sidedness of the anticolonialism interpretation. In fact, say Reitsma and Kleinpenning, "Another point in Lacoste's favor is the

emphasis he places on the harmful role played by colonialism while at the same time bringing out the relative importance of that same factor. By drawing attention to the part played by third world elites, he makes more understandable the lack of progress during the postcolonial period as well as the limited development in third world countries which never were colonies" (p. 235).

The book does have a few flaws in my judgment. On page 33, Reitsma and Kleinpenning speak of the problem of "an excessively large and for the most part unproductive, even parasitical, informal tertiary sector." This is certainly an incomplete view. Much later (p. 164), they, in fact, speak much more positively of this informal sector. Unfortunately, neither De Soto nor Hirschman appears in their extensive list of references.

In several instances they seem to focus on Africa and south-southeast Asia but generalize for the third world as a whole. For example, "In nearly every Third World country, over half the working people are engaged in agriculture and in many at least 75 percent are so employed" (p. 52). This is an inaccurate generalization for Latin America. The sharp dichotomy between large agricultural enterprises producing for the market and subsistence farmers who can barely feed themselves from their production (pp. 96, 102) seems overdrawn for most areas of the less developed world. The Green Revolution is, I believe, underrated (pp. 80-85), and no mention is made of the network of international agricultural research centers. Finally, I fail to understand the need for a questionable comparison which is found on the very first page (p. 3) of chapter 1: "Partly because Europeans are exposed to more information on the low quality of life in the Third World and partly because they live in a more socialistically minded environment, they tend to be more inclined than Americans to sympathize with, and provide economic support to, the poor and hungry in Africa, Asia and Latin America."

Despite several overgeneralizations, this is a good book and should be a useful supplementary reader for courses in development studies.

Sicular, Terry, ed. *Food Price Policy in Asia: A Comparative Study*. Ithaca NY: Cornell University Press, 1989, viii + 307 pp., \$49.95, \$16.95 paper.

"The aim of this book is to understand food pricing and through it broader food policy choices in a variety of country settings . . . the chapters have been written to a common outline and share a common perspective . . . food price policy is defined to include both explicit price interventions and macroeconomic, exchange-rate, and trade policies" (p. vii). The six Asian country studies, written by authors with considerable research experience in their respective areas of expertise, are China, Indonesia, Nepal, the Philippines, South Korea, and Thailand. The latter half of the above definition of price policy is critical for the chapter outlines, which, according to Sicular, draw heavily from the ideas of Timmer, Falcon, and Pearson in *Food Policy Analysis*; the effects of these economy-wide policies are dealt with at some length in all of the chapters and constitute the main focus of attention in the Korean and Philippine chapters. The common outline includes a discussion of (a) policy objectives; (b) price policy instruments (output price supports, consumer subsidies, input price subsidies usually for fertilizer, macroeconomic, and trade policies); and (c) policy outcomes and tradeoffs between conflicting policy objectives (urban consumption, producer incomes, price stability, self-sufficiency and food security, government revenues, rapid economic development).

A central question addressed by the authors is whether "distorted" agricultural prices hinder agricultural and overall economic development—how important is "getting prices right?" Kym Anderson (Korea, where agriculture is protected) and Christina David (the Philippines, where agriculture is taxed) take strong positions that past price distortions resulted in serious inefficiencies. Peter Timmer contends that most of the benefits of the agricultural research and investment program in Indonesia would not have been realized without implementation of the more favorable price environment after the mid-1960s that substantially reduced but did not entirely eliminate biases against agriculture. Theodore Panayotou (Thailand) argues that agriculture grew strongly despite substantial taxation of rice exports because of the compensating factors of free irrigation water and free land for expansion; however, the rising costs of bringing new land under cultivation and irrigation will not permit a continuation of past pricing policies with the same favorable outcome.

In Nepal, with its long, open border with India, the question is to some extent irrelevant. Michael Wallace presents the apt analogy of the flea (Nepal) that travels in the elephant's (India) direction, whichever way the flea turns on the elephant's back. Terry Sicular chooses not to criticize directly (or praise) China's policy of taxing food production through various quota arrangements but instead is satisfied to lay out the resulting tradeoffs in policy outcomes.

The brief concluding chapter is disappointing in that Sicular is content merely to summarize the complexities of food price policy formulation—in some sense recapitulating the objectives-instruments-outcomes

framework of Timmer, Falcon, and Pearson with specific examples from the case studies. A comparative analysis of several empirical applications of that framework might have identified common tendencies that would have allowed predictions/rules/hypotheses of government behavior in carefully defined situations. After providing some relevant cross-country background information, a much longer introductory chapter makes a start at this, but the concluding chapter fails to follow up.

The job of identifying these common tendencies would be made easier in my opinion by a more in-depth treatment in the case studies of three areas. First, the development and dissemination of modern varieties of rice allowed policy makers in three countries to compensate rice producers for rice prices which were kept artificially low. Second, relatively little empirical information is provided on consumption effects; it would have been useful to discuss urban-rural tradeoffs in terms of four groups: urban and rural poor and urban and rural wealthy. Third, it is these latter two groups that usually vie for political influence along with the public bureaucracy, the military, and international interests; a short summary of the mechanisms through which the political system in each of these countries mediates these competing concerns would have been helpful.

The strength of the book lies in the wealth of information that is contained in the six country studies, which organize and summarize past research (often the author's own research) on a broad range of country-specific food price policy issues. Each chapter provides a valuable reference for persons interested in food policies in that country. The Indonesian chapter is exemplary in its even treatment of the large number of factors that can bear upon food policy formation, blending theory and empirical evidence into a compelling, understandable story despite its complexity. The Korean chapter is also noteworthy for the persuasive empirical evidence that it presents in measuring the costs of agricultural protection and for its elucidation of why particular policies emerge from the political process.

Area-Yield Crop Insurance Reconsidered

Mario J. Miranda

One of the more promising proposals for reforming the federal crop insurance program calls for both premium rates and indemnities to be based not on the producer's individual yield but rather on the aggregate yield of a surrounding area. Area-yield crop insurance can provide more effective yield-loss coverage than individually tailored insurance, without most of the adverse selection and moral hazard problems that have historically undermined the actuarial performance of the federal crop insurance program.

Key words: crop insurance, optimal hedging, risk and uncertainty.

When the Federal Crop Insurance Act of 1980 was signed into law, policy makers envisioned a crop insurance program that would ultimately operate on a near actuarially sound basis with limited government financial assistance.¹ Between 1980 and 1988, however, government outlays for the federal crop insurance program exceeded 4.2 billion dollars, accounting for over 80% of the total indemnities paid to producers. The loss ratio, indemnities paid to producers divided by premiums collected from producers, averaged 2.05, well in excess of the approximate 0.95 level generally regarded as necessary for break-even insurance operations (U.S. GAO).¹ The poor actuarial performance of the federal crop insurance program and its failure to attract producer participation has led to dissatisfaction with the program, including calls for the repeal of the 1980 act and elimination of federal crop insurance.²

Under the provisions of the 1980 act, crop insurance is marketed primarily through private

insurance agents and brokers. The 1980 act authorized the Federal Crop Insurance Corporation to subsidize producer premium payments and to reimburse participating private insurance companies for their administrative expenditures and part of their underwriting losses. Federal crop insurance, which is available for over fifty crops, covers all natural risks, including unavoidable losses from drought, excessive rain, and storm damage. An agricultural producer can purchase individualized coverage for either 50%, 65%, or 75% of the normal yield, and at one of three different price elections. If the producer's yield falls below the elected coverage level, he receives, per insured acre, an indemnity equal to the yield shortfall times the elected price level.

The failure of the federal crop insurance program to operate on an actuarially sound basis can be attributed to the problems inherent in trying to tailor coverage to individual yield-loss experience. The most serious of these problems, adverse selection, arises because producers are better informed about the distribution of their own yields and thus are better able to assess the actuarial fairness of their premiums than the insurer, who lacks access to reliable individual yield data and other relevant information (Skees and Reed). Producers who recognize that their expected indemnities exceed their premiums are more likely to purchase coverage than those whose premiums are actuarially high. As a result, the insurer's expected indemnity outlays exceed total premium income, and, in the long run, the insurance operation loses money. Efforts by the insurer to avoid these losses by raising premiums only result in a smaller and more adversely selected pool of participants.

Mario J. Miranda is an assistant professor in the Department of Agricultural Economics and Rural Sociology, Ohio State University.

Research was supported by U.S. Department of Agriculture Cooperative Research Agreement 58-3AEK-7-80020.

The author wishes to thank Joseph Glauber, Jerry Skees, and an anonymous reviewer for their valuable suggestions and comments and Jean Buzby for her assistance with the data.

¹ If government premium subsidies are included in the total premium payment, as is common practice, the loss ratio would be 1.57. Excluding the subsidies, as occurs here, provides a better measure of the current program's failure to operate on an actuarially sound basis. The 0.95 loss ratio target assumes that a loading factor of 5% is sufficient to cover administrative expenses.

² The Bush administration's 1990 farm bill proposal calls for repeal of the Federal Crop Insurance Program and replacing it with a standing disaster assistance program.

Other problems associated with individual-yield crop insurance include high administrative costs and moral hazard. Record keeping and other manpower requirements needed to verify individual production histories and to adjust individual yield-loss claims raise insurer expenditures and impose transactions costs on participating producers. Moral hazard occurs when producers, after purchasing insurance, alter their production practices in a manner that increases their chances of collecting an indemnity (Chambers, Nelson and Loehman). In order to combat moral hazard, federal crop insurance requires a deductible of at least 25% of the producer's normal yield. This provision limits the coverage provided by the insurance and reduces its value to the individual producer.

Area-Yield Crop Insurance

The fundamental problems that accompany individual-yield crop insurance have been known since the early days of the federal crop insurance program. Halcrow, in his 1949 evaluation of the effectiveness of the federal crop insurance program's first decade of operation, concluded that individual-yield crop insurance "will work in a satisfactory manner only under a system of conditions so exacting in their specification that they will be found to a rather limited extent in American agriculture" (p. 476).

In his paper, Halcrow promoted an alternative crop insurance scheme in which both indemnities and premiums would be based not on a producer's individual yield but rather on the aggregate yield of a surrounding geographical area. Under a so-called area-yield plan, a participating producer would receive, in any given year, an indemnity equal to the difference, if positive, between the area yield and some predetermined critical yield level. Every participating producer in a given area would receive the same indemnity per insured acre, regardless of his own crop yield, and therefore would pay the same premium rate.³

Area-yield crop insurance offers numerous

advantages over individual-yield crop insurance. Because information regarding the distribution of the area yield is generally available and more reliable than information regarding the distributions of individual yields, insurers could more accurately assess the actuarial fairness of premiums under an area-yield policy, thereby significantly reducing adverse selection problems.⁴ Moreover, because the indemnities would be based on the area yield rather than the producer's yield, a producer could not significantly increase his indemnity by unilaterally altering his production practices. Thus, under an area-yield insurance program, moral hazard essentially would be eliminated. Administrative costs would also be substantially reduced under an area-yield program because claims would not have to be adjusted individually and verification of individual production histories would no longer be required.⁵

In the following sections, a theoretical framework for evaluating the effectiveness and equity of area-yield crop insurance is developed and applied to western Kentucky soybean producers in an empirical illustration. Several questions are addressed: How efficiently, relative to individual-yield crop insurance, does area-yield crop insurance cover individual yield risk? How does the risk reduction effectiveness of area-yield crop insurance vary across producers? How can a producer optimize coverage under an area-yield plan? The article concludes with recommendations on how area-yield crop insurance might be implemented.

Theoretical Analysis

Consider a producer i whose yield \tilde{y}_i is random due to the uncertain effects of weather and other natural phenomena. Suppose the producer operates in an area where the average yield across all farms is \bar{y} . By orthogonally projecting the producer's individual yield \tilde{y}_i onto the area yield \bar{y} , an identity that relates the two is obtained:

$$(\cdot) \quad \tilde{y}_i = \mu_i + \beta_i \cdot (\bar{y} - \mu) + \tilde{\epsilon}_i.$$

³ The program examined in this paper should not be confused with the Federal Crop Insurance Corporation's practice prior to 1981 of writing coverage provisions using area yield data while basing indemnities on individual yield experience. We adopt Halcrow's original usage of the term "area-yield" to refer to a program in which coverage, premiums, and indemnities are all based on area yield experience.

⁴ These include intertemporal adverse selection problems, which arise under the current program when producers make participation decisions based on information that they hold privately at planting time, such as the soil moisture levels on their own land.

⁵ In its recent study, the Commission for the Improvement of the Federal Crop Insurance Program cites many of these advantages and recommends that an area-yield crop insurance pilot program be implemented on an experimental basis in selected areas.

Here,

$$(2) \quad \beta_i = \text{Cov}(\tilde{y}_i, \bar{y}) / \sigma_{\bar{y}}^2$$

$$(3) \quad E\tilde{\epsilon}_i = 0 \quad \text{Var}(\tilde{\epsilon}_i) = \sigma_{\tilde{\epsilon}_i}^2 \quad \text{Cov}(\bar{y}, \tilde{\epsilon}_i) = 0$$

$$(4) \quad E\tilde{y}_i = \mu_i \quad \text{Var}(\tilde{y}_i) = \sigma_{\tilde{y}_i}^2$$

$$(5) \quad E\bar{y} = \mu \quad \text{Var}(\bar{y}) = \sigma_{\bar{y}}^2$$

The coefficient β_i measures the sensitivity of the producer's individual yield to the systemic factors that affect the area yield. Equation (1) decomposes individual yield variation into a systemic component $\beta_i \cdot (\bar{y} - \mu)$ that is perfectly correlated with the area yield and a nonsystemic component $\tilde{\epsilon}_i$ that is uncorrelated with the area yield.

Suppose that the producer is offered area-yield crop insurance in which the indemnity and the premium are both denominated in production units, say, bushels per acre.⁶ The producer purchases coverage at a premium rate of π bushels per acre. If the area yield \bar{y} subsequently falls below a critical yield level y_c , he receives an indemnity \bar{n} , in bushels per insured acre, equal to the shortfall:

$$(6) \quad \bar{n} = \max(y_c - \bar{y}, 0).$$

Assume that the premium π is actuarially fair;⁷ that is, it is equal to the expected indemnity $E\bar{n}$.

With area-yield crop insurance, the producer's net yield equals

$$(7) \quad \bar{y}_i^{\text{net}} = \tilde{y}_i + \bar{n} - \pi,$$

and his yield risk, as measured by the variance of the net yield, equals

$$(8) \quad \text{Var}(\bar{y}_i^{\text{net}}) = \sigma_{\tilde{y}_i}^2 + \sigma_{\bar{n}}^2 + 2 \cdot \text{Cov}(\tilde{y}_i, \bar{n}),$$

where $\sigma_{\bar{n}}^2 = \text{Var}(\bar{n})$ is the variance of the indemnity. By acquiring area-yield insurance, the producer thus reduces his yield risk by an amount

$$(9) \quad \Delta_i = \text{Var}(\tilde{y}_i) - \text{Var}(\bar{y}_i^{\text{net}}) = -\sigma_{\bar{n}}^2 - 2 \cdot \text{Cov}(\tilde{y}_i, \bar{n}).$$

⁶ Although straightforward, generalizing the model to account for price variation would undermine the clarity of the exposition while providing little additional insight into the structure of area-yield insurance.

⁷ Assuming that the premium is actuarially fair allows us to evaluate the insurance coverage solely in terms of its variance reduction, provided we further assume, if only as a first-order approximation, that producers are mean-variance utility maximizers. Meyer has shown that mean-variance decision models are consistent with expected-utility maximization under much weaker behavioral restrictions than had previously been thought.

Assume now that the individual nonsystemic yield component $\tilde{\epsilon}_i$ and the area yield \bar{y} are conditionally independent (a mild assumption given that they are uncorrelated by definition). Then the individual nonsystemic yield component $\tilde{\epsilon}_i$ and the indemnity \bar{n} are uncorrelated, and it follows from (1) that

$$(10) \quad \text{Cov}(\tilde{y}_i, \bar{n}) = \beta_i \cdot \text{Cov}(\bar{y}, \bar{n}).$$

Defining

$$(11) \quad \beta_c = - \frac{\sigma_{\bar{n}}^2}{2 \cdot \text{Cov}(\bar{y}, \bar{n})}$$

and substituting (10) into (9), the risk reduction obtained from area-yield insurance can be rewritten as follows:

$$(12) \quad \Delta_i = \sigma_{\tilde{y}_i}^2 \cdot \left[\frac{\beta_i}{\beta_c} - 1 \right].$$

We refer to β_c as the critical beta. Because the area-yield \bar{y} and the indemnity \bar{n} are negatively correlated, $\beta_c > 0$. Moreover, because the critical beta β_c and the variance of the indemnity $\sigma_{\bar{n}}^2$ are determined by the distribution of the area yield \bar{y} and the critical yield y_c , they are invariant among producers within a given area. It thus follows from (12):

PROPOSITION 1. *For a given critical yield y_c , the risk reduction obtained by producer i from area-yield insurance is completely determined by, and is positively related to, his individual beta, β_i .*

It also follows from (12) that:

PROPOSITION 2. *Area-yield insurance is risk reducing for producer i if and only if $\beta_i > \beta_c$, that is, if and only if his individual beta exceeds the critical beta.*

Thus, producers with high β_i 's can expect significant reduction in yield risk from purchasing area-yield insurance, whereas those with low β_i 's may actually find that area-yield insurance is risk augmenting. A characterization of β_i that is helpful in understanding the significance of the above results is given by

$$(13) \quad \beta_i = \rho_i \cdot \frac{\sigma_{\tilde{y}_i}}{\sigma_{\bar{y}}},$$

where ρ_i is the coefficient of correlation between producer i 's yield \tilde{y}_i and the area yield \bar{y} . As an

immediate consequence of proposition 1 and (13) we have:

PROPOSITION 3. *Ceteris paribus, the more highly correlated a producer's yield is to the area yield, the greater the risk reduction that the producer can obtain from area-yield insurance.*

PROPOSITION 4. *Ceteris paribus, the higher a producer's yield variance, the greater the risk reduction that the producer can obtain from area-yield insurance.*

To ascertain how the risk reduction obtained from area-yield insurance varies across producers within a given area, we must determine how the β_i are distributed within the area and how the critical β_c varies with the critical yield y_c . Although definitive answers to both of these questions can only be obtained empirically, some light can be shed from theoretical considerations.

Consider first the distribution of the β_i 's. If ω_i denotes the proportion of total acreage in the area planted by producer i , then, by definition, $\sum_i \omega_i = 1$ and $\sum_i \omega_i \cdot \bar{y}_i = \bar{y}$, so that

$$(14) \quad \sum_i \omega_i \cdot \text{Cov}(\bar{y}_i, \bar{y}) = \text{Cov}\left(\sum_i \omega_i \cdot \bar{y}_i, \bar{y}\right) \\ = \text{Cov}(\bar{y}, \bar{y}) = \sigma_{\bar{y}}^2.$$

Dividing both sides by $\sigma_{\bar{y}}^2$ and using (2), it follows that

$$(15) \quad \sum_i \omega_i \cdot \beta_i = 1.$$

Thus, the acreage weighted average of the β_i within any area is always one. The dispersion of the β_i and the skewness in the their distribution, on the other hand, may vary among regions and ultimately can only be determined empirically. Intuition suggests that the more homogeneous are the soil and climatic conditions faced by producers in a given area, the more closely the β_i s will cluster around one.

Under mild regularity conditions, the critical beta β_c is an increasing function of the critical yield y_c .⁸ In general, it can be shown that⁹

$$(16) \quad 0 \leq \beta_c \leq 0.5, \text{ and}$$

$$(17) \quad \lim_{y_c \rightarrow 0} \beta_c = 0.0 \quad \text{and} \quad \lim_{y_c \rightarrow \infty} \beta_c = 0.5.$$

⁸ The regularity condition holds for reasonable parameterizations of the lognormal and beta distributions often used to describe yield distributions and has been verified for the empirical distributions of 1974–86 U.S. soybean yields for all U.S. soybean-producing counties.

⁹ Formal proofs of (16) and (17) are available from the author upon request.

It thus follows from proposition 2 that area-yield insurance will be risk reducing for any producer i from whom $\beta_i > 0.5$. Since the average β_i within an area is 1, most producers should find area-yield insurance risk reducing. Area-yield insurance is definitively risk augmenting only if $\beta_i \leq 0$, that is, only if a producer's yield is negatively correlated with the area yield. If $0 < \beta_i \leq 0.5$, area-yield insurance may or may not be risk reducing, depending on the critical yield level y_c ; the higher the critical yield y_c , the more likely that area-yield insurance will be risk reducing.

Until now, we have implicitly assumed that producers cover exactly 100% of their acreage when they purchase crop insurance. Suppose now that producer i is free to elect a coverage level ϕ_i that may be more or less than 100%. At this coverage level, producer i 's net yield is

$$(18) \quad \bar{y}_i^{\text{net}} = \bar{y}_i + \phi_i \cdot \bar{n} - \phi_i \cdot \pi$$

and the risk reduction obtained from area-yield insurance is

$$(19) \quad \Delta_i = \text{Var}(\bar{y}_i) - \text{Var}(\bar{y}_i^{\text{net}}) \\ = -\phi_i^2 \cdot \sigma_{\bar{n}}^2 - 2 \cdot \phi_i \cdot \text{Cov}(\bar{y}_i, \bar{n}).$$

Substituting (10) into (19), the risk reduction can be rewritten more conveniently

$$(20) \quad \Delta_i = \sigma_{\bar{n}}^2 \cdot \left[\frac{\beta_i}{\beta_c} \cdot \phi_i - \phi_i^2 \right].$$

Maximizing this expression with respect to the coverage level, it follows that:

PROPOSITION 5. *If the coverage level is optional under an area-yield plan, then producer i minimizes his yield risk by selecting a coverage level*

$$(21) \quad \phi_i^* = \frac{\beta_i}{2 \cdot \beta_c}.$$

Thus, if the producer is free to choose his coverage level, save that it be positive, he can reduce his yield risk using area-yield insurance if and only if his beta is positive, that is, if and only if his yield is positively correlated with the area yield. In this case, since the critical beta β_c rises with the critical yield y_c , the producer's optimal coverage level will fall with the critical yield. Since the critical beta β_c is bounded above by one-half, the producer's optimal coverage level will approach but will never drop below β_i . And thus, since the average β_i is 1, one can expect that coverage in excess of 100% will be optimal for a significant portion of, if not most, producers.

Substituting (21) into (20) and solving gives the following result:

PROPOSITION 6. *If the coverage level is optional, then the maximum risk reduction that producer i can obtain from area-yield insurance is*

$$(22) \quad \Delta_i^* = \rho^2 \cdot \beta_i^2 \cdot \sigma_{\bar{y}}^2,$$

where ρ is the correlation coefficient between the indemnity \bar{n} and the area yield \bar{y} .

Because the area yield \bar{y} and the individual nonsystemic yield component $\bar{\epsilon}_i$ are uncorrelated, it follows from (1) that

$$(23) \quad \sigma_{\bar{y}_i}^2 = \beta_i^2 \cdot \sigma_{\bar{y}}^2 + \sigma_{\bar{\epsilon}_i}^2.$$

That is, yield risk without crop insurance can be decomposed into a systemic component $\beta_i^2 \cdot \sigma_{\bar{y}}^2$ and a nonsystemic component $\sigma_{\bar{\epsilon}_i}^2$. Since $0 \leq \rho^2 \leq 1$, proposition 6 implies that area-yield crop insurance, in effect, eliminates a portion of systemic yield risk faced by the producer but none of the nonsystemic yield risk. Since ρ^2 is invariant across producers, it follows that:

PROPOSITION 7. *If the coverage level is optional, then the maximum risk reduction that can be obtained from area-yield insurance, as a proportion of systemic yield risk, is the same for every producer.*

Empirical Application

We now illustrate how area-yield crop insurance might perform in practice using individual farm-level yield data for 102 western Kentucky soybean producers.¹⁰ The producers are assumed to comprise the entire population of the "area" in which area-yield crop insurance is offered. All performance estimates are derived directly from the empirical yield distributions; a parametric distribution is not fitted to the data.

Table 1 shows how the critical beta for the 102-farm area varies with the level of the critical yield. Critical yields are expressed both in bushels per acre and as a percentage of the normal or expected area-wide yield of 30.7 bushels per acre. As seen in table 1, the critical beta rises as the critical yield is increased. For sufficiently low critical yields, the critical beta

Table 1. Critical Beta, Per-Acre Premium, and Average Optimal Coverage Under an Area Yield Plan, Selected Critical Yields

Critical Yield		Critical Beta	Premium (bu./acre)	Average Optimal Coverage (%)
Percent of Normal	Bushels per Acre			
60	18.4	0.00	0.00	
65	20.0	0.04	0.06	1329
70	21.5	0.10	0.17	506
75	23.1	0.16	0.27	312
80	24.6	0.22	0.37	227
85	26.1	0.25	0.60	198
90	27.7	0.28	0.96	178
95	29.2	0.31	1.47	160
100	30.7	0.36	2.04	138
105	32.3	0.41	2.77	123
110	33.8	0.44	3.70	112
115	35.4	0.48	4.80	104
120	36.9	0.50	6.18	101
125	38.4	0.50	7.69	100

achieves its theoretical minimum of zero and, for sufficiently high critical yields, achieves its theoretical maximum of one-half.

Table 1 also shows that the actuarially fair premium under a full coverage area-yield plan (or, equivalently, the expected per-acre indemnity) rises with the critical yield level. For sufficiently low critical yields, area-yield insurance is completely ineffective and the fair premium is zero; for sufficiently high critical yields, a one bushel increase in critical yield simply raises the expected indemnity, and therefore the fair premium, by the same amount.

Table 1 also shows how the optimal level of coverage under an optional area-yield plan varies with the critical yield level. Because the optimal coverage level varies among producers, only the average coverage level across producers is reported. For example, given a critical yield equal to 90% of normal, producers, on average, minimize their yield risk by purchasing coverage for 178% of their acreage. That is, on average, producers minimize their yield risk by purchasing insurance for 78% more acreage than they actually plant. If the critical yield is set too low, area-yield insurance will be ineffective and the optimal coverage level will be zero. If the critical yield is set sufficiently high, the average optimal coverage level will equal 100%. In intermediate cases, the average optimal coverage level exceeds 100% and falls as the critical yield rises.

Figure 1 shows the distribution of individual betas for the 102 producers comprising the area

¹⁰ The yield data, which were provided by Jerry Skees of the University of Kentucky, cover the period 1974–88 and were adjusted for secular trends to reflect 1988 production levels.

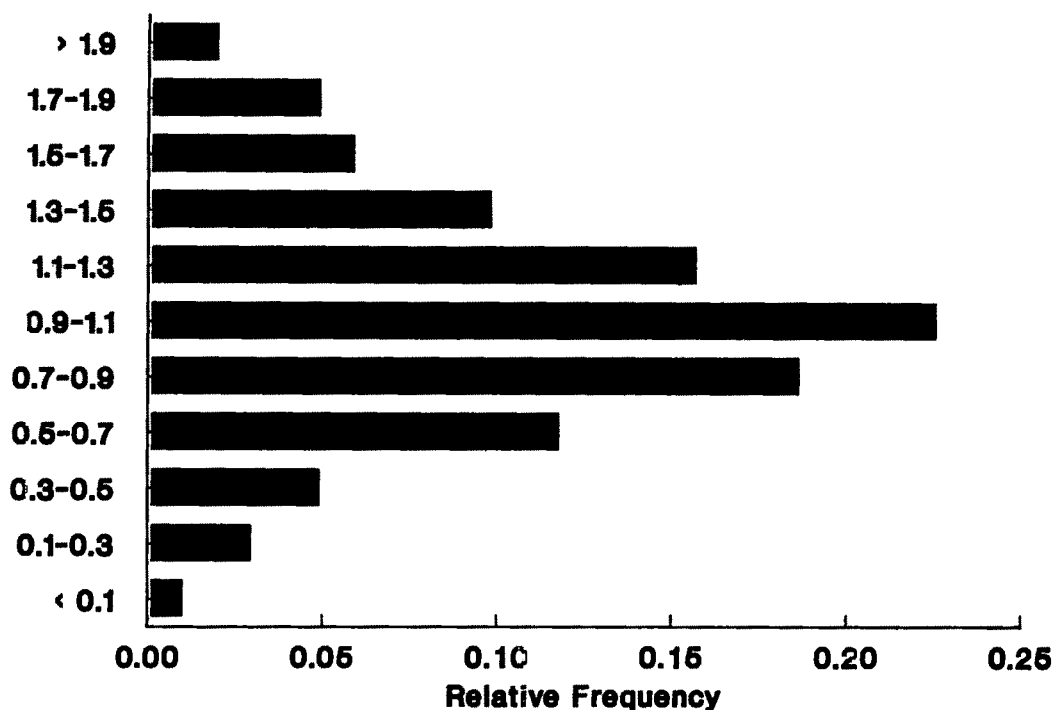

Beta Range

Figure 1. Frequency distribution of individual producer betas

population. The distribution of the betas possesses a regular, bell shape which is centered on one and exhibits no discernable skewness. Of the 102 producers in the sample, 5 have betas falling below 0.28, the critical betas for a full coverage area-yield plan with a critical yield equal to 90% of normal; for those individuals, a full coverage area-yield plan would offer no protection against yield risk. Of the 5 producers, however, 4 have positive betas, indicating that they would obtain some yield risk reduction from an area-yield plan if they could select their levels of coverage optimally.¹¹

We now turn to a comparison of specific versions of an individual-yield plan (IYP) and full coverage and optimal coverage area-yield plans (AYP). Under the IYP, each producer is assumed to choose a yield guarantee equal to 75% of his normal yield, the highest yield election

level available under the current Federal Crop Insurance Program. Under the IYP, whenever a producer's own yield falls below 75% of his normal yield, he receives an indemnity equal to the shortfall.

Under the full coverage AYP, as under the IYP, each producer purchases coverage for exactly 100% of his acreage. The critical yield under the full coverage AYP is set at 88.5% of the normal area yield, indicating that whenever the area yield falls below 88.5% of normal, each producer, regardless of his own yield, receives an indemnity equal to the shortfall in the area yield. A critical yield of 88.5% assures, though only for the present empirical application, that the fair premium paid by each producer under a full coverage AYP is equal to the average fair premium paid by producers under the 75% IYP.¹²

Under the optimal coverage AYP, producers choose their level of coverage and are assumed

¹¹ The 102 farms in the sample are spread over a twenty-county area. Participants in an AYP implemented on a county level would likely be more homogenous with respect to soil and climatic conditions and thus should exhibit less dispersion in their individual betas. One would therefore expect an AYP to perform better than is indicated in this empirical application.

¹² Since individual yields tend to be more variable than the aggregate area yield, an individual yield plan with a given yield guarantee will pay an indemnity more often and thus will require a higher premium than an area-yield plan whose critical yield is the same.

to do so in a manner that minimizes their yield risk. The critical yield under the optimal coverage AYP is assumed to equal 95% of the normal area yield, indicating that whenever the area yield falls below 95% of normal, each producer, regardless of his own yield, receives an indemnity equal to the shortfall in the area yield times his elected level of coverage.

Table 2 shows the actuarially fair premium rates per planted acre under the IYP and the two AYPs for selected producers.¹³ Under the IYP, fair premiums are based on individual yield experience and thus vary among producers. Under a full coverage AYP, the premium is based on the area yield experience and thus is the same for all producers. Under both the IYP and full

coverage AYP, the average premium paid by producers is 0.83 bushels per planted acre, about 2.7% of the normal area yield. Under the optional coverage AYP, the optimal level of coverage per planted acre, and thus the fair premium, varies among producers. The average optimal coverage level across producers is 160%; the additional coverage raises the average premium paid by producers to 2.35 bushels per planted acre.

Table 3 gives the percentage reduction in individual yield risk for selected producers under the three alternative crop insurance plans. As seen in the table 3, risk reduction is greater, on average, under the optimal coverage AYP than under either the IYP or the full coverage AYP. Under the optimal coverage AYP, the average risk reduction is about 39.1%. In contrast, the IYP reduces risk by 30.8% on average and the full coverage AYP by 22.4%.

The relative performance of the three pro-

¹³ Because of adverse selection and heavy government subsidization, most producers under the current crop insurance program pay premiums that are significantly less than their expected indemnity.

Note: See note, table 1.

^a Variance measured in bushels per acre squared.

grams varies among producers. Table 3 confirms that producers with the highest betas tend to enjoy the greatest relative risk reduction under the optimal AYP, whereas producers with the highest yield variances tend to enjoy the greatest relative risk reduction under the IYP. The correlation coefficient between the risk reduction obtained under the IYP and that obtained under the optimal AYP is only 0.06, indicating little relation between the risk reduction benefits from one program as compared to the other. Both small and large producers will tend to prefer the optimal AYP to the IYP, but the latter appear to enjoy the greatest benefit from moving to the optimal AYP from the IYP. For the largest twenty-three producers, who account for half the acreage planted, the optimal AYP offers an average risk reduction of 40.1% and the IYP an average of 28.8%. For the smallest seventy-eight producers, the optimal AYP offers an average risk reduction of 37.3% and the IYP an average of 32.7%.

Additional Considerations

Strictly speaking, an AYP is not a true insurance program since payments to producers are not based on their own specific yield losses. Instead, an AYP is more accurately described as a hedging instrument. Specifically, an AYP is like a put option in which the critical yield plays the role of the strike price. More precisely, because each individual's yield is a constituent of the area yield, an AYP offers a hedge against individual yield-loss in the same way that an option on a stock futures index offers a hedge against the price risk of holding one of the stocks in the index.¹⁴

While characterizing the AYP as a hedging

¹⁴ With slight modification, many of the results in this paper generalize to crop insurance schemes in which indemnities are based on weather variables such as rainfall or temperature. Such schemes have been proposed in the past (Sanderson, Lee) but have failed to gain acceptance among policy makers.

instrument helps put the form and function of the AYP into perspective, it also points to some difficulties that may arise in having the program accepted by producers. Given that producers are notorious for shunning options and futures markets as means of hedging price risk, it is likely that an AYP would not automatically enjoy widespread acceptance among producers as a means of hedging yield risk. Ultimately, to achieve high rates of participation, AYPs may have to be subsidized or made a cross-compliance provision of government commodity stabilization programs.

Should producers be free to select their coverage levels under an AYP, and how high should the critical yield level be set? These two important questions regarding the implementation of an AYP are closely related. Under an IYP, a deductible, or equivalently, a yield guarantee well below the producer's normal yield, is necessary to guard against the moral hazard; for the same reason, coverage levels exceeding 100% of acreage planted cannot be permitted. Under an AYP, however, moral hazard is essentially eliminated; only through illegal and widespread collusive action by producers could the area yield be significantly reduced.¹⁵ Accordingly, optional coverage levels and high critical yields are feasible under an AYP. Since, as shown above, producers can reduce yield risk by choosing coverage levels in excess of 100%, it seems sensible that coverage levels be optional under an AYP. In addition, because the risk reduction under an optimal AYP rises for all individuals as the critical yield is increased, a high critical yield level is indicated.

The higher premiums that producers would pay under an AYP for increased coverage and a higher critical yield need not be a major concern to producers: if the premium is actuarially fair, then producers can expect to recover the higher premium through higher indemnities while enjoying the benefits of reduced yield risk. There are, however, some potential problems that the government may face if critical yield levels are high and optional coverage is permitted under an AYP. First, coverage levels in excess of 100% and critical yields in excess of the normal yield would be difficult to rationalize politically, particularly if the AYP is promoted as an insurance program. Second, higher critical yields and cov-

erage levels would raise the level and variability of total indemnity outlays. Thus, whether the government acts as a direct insurer or reinsurer, substantial yield risk could ultimately be transferred to the government, raising the variability of federal budgetary outlays.

Risk reduction under an optimal AYP varies among producers, raising questions about the equity of such a program. Recall, however, that an optimal coverage AYP would reduce systemic yield risk in the same proportion for all producers. If areas are defined so as to be homogenous with regard to soil and climatic conditions, then nonsystemic yield risk would be attributable almost exclusively to producer-specific factors such as choice of production practice. It is arguable, therefore, that the proper goal for a government crop insurance program should be the reduction of systemic risk, not total risk; otherwise, the program would promote a misallocation of societal resources by encouraging risky production. Thus, if areas are properly defined, an optimal coverage AYP will be equitable in a socially meaningful way.

Because of the abundance of reliable historical yield data and the pre-existence of administrative structures, the most practical definition of area under an AYP will likely be the county. If the AYP is administered on a county basis, the maximum efficacy and equity of the AYP will be achieved in counties that are homogenous with regard to soil and climate. In some regions, however, area boundaries that cut across established county lines may be needed for the AYP to function well. Regardless of how areas are determined, however, it is conceivable that some producers will find the yield of an adjacent area more representative of their own individual yields. In such cases, the producers would improve their coverage by participating in the AYP of the adjacent area and thus should not be discouraged from doing so.

Concluding Comments

An individual producer's total yield risk can be decomposed into a systemic component that is explained by factors affecting all producers in his area and a nonsystemic residual component. Individual-yield crop insurance, such as the one currently underwritten by the federal government, covers total individual yield risk but is limited in its effectiveness by the large deductibles that must be imposed in order to combat moral hazard. Area-yield crop insurance would

¹⁵ A collusive arrangement would be difficult to sustain since a noncolluding producer could maximize his individual yield and still obtain the benefits of the higher indemnity brought about by the actions of the colluding producers.

cover only systemic individual yield risk but would also be free of moral hazard and thus would not require large deductibles or limits on coverage levels. For most producers, the improved coverage of systemic yield risk obtained through lower deductibles and higher coverage under an area-yield plan would outweigh the nonsystemic yield risk protection provided by an individual-yield plan. That is, for most producers, area-yield insurance would provide better overall yield risk protection than individual-yield insurance.

Because information pertaining to the distribution of an area yield is not privately held and is generally available, the asymmetric information problems that have given rise to adverse selection under the current federal crop insurance program would be significantly reduced under an area-yield program. The reduction of adverse selection and the virtual elimination of moral hazard would significantly improve the actuarial performance of the federal crop insurance program. Moreover, because verification of individual production histories and adjustment of individual yield-loss claims would not be necessary under an area-yield program, an area-yield crop insurance program would be less expensive to administer.

The evidence presented in this paper suggests that area-yield crop insurance should receive serious consideration as an alternative to the current crop insurance program. At the very least, area-yield crop insurance should be examined on an experimental basis with long-term pilot programs established for regions where tradi-

tional crop insurance has historically performed poorly.

Scientific Principle and Practice in Agricultural Economics: An Historical Review

Harold F. Breimyer

Ever since their field of learning took its own identity, agricultural economists have seen themselves as dedicated to the scientific principle. In early years that commitment was trusted as a guard against human fallibility, and the more so as the first investigations relied heavily on statistical data and analyses—supposedly bias-free. Thus originated a lasting emphasis on the quantitative. A need for underlying economic principles, recognized at once, was developed in depth beginning in the 1950s. Research taxonomies, outlined in the 1920s, devolved later into an array of research methods. Scientific practice is viewed also as how scientists “behave,” and writings about agricultural economists’ record are couched in terms of values, objectivity, ethics. Despite just claims to systematic rigor, science responds also to unsystematic elements, among them imagination and hunch. Most engaging in literature are never-ending exchanges about the merits of mathematics and model building.

Key words: research methods, scientific principle.

Agricultural economists are diverse and can be disputatious, but they have one common bond. They see themselves as functioning in the realm of science and dedicated to the scientific principle.

It is, therefore, something of an anomaly that in the annals of their discipline, inquiries into the meaning of that principle and its significance to their field are reported only episodically. It is as though, having embraced the doctrine of science, practitioners in agricultural economics have felt little need to meditate on how their endeavors fit into the schema of learning known as science, or even to ponder what that schema means. Nor do they anguish over what constraints are thereby placed on them.

With a slight literary license the history of agricultural economics can be said to be a sequence of counting, correlation, and econometrics. The early years of collection of data were followed by a decade of fascination with correlation and then by a long dedication to econometrics with all its model building and intricate statistical analysis. There may be whimsy in the lexicography of the three terms, which are of

Middle English, Latin, and Greek origins, respectively. Is the profession reverting to its roots?

The earliest professional writing in agricultural economics had the simplest of themes. It was to “get the facts,” which in most instances were numerical. That focus led to a major emphasis on data gathering, that proved also to be precedent setting as it established a lasting predilection for quantitative analytical techniques.

In 1963 Don Paarlberg scolded agricultural economists for their bent to quantify everything and omit the nonquantifiable (p. 1390). But quantitative studies continued to crowd non-quantitative ones out of the pages of the *American Journal of Agricultural Economics*, particularly the four quarterly issues.

From the early emphasis on numbers, an inference can be drawn that has never vanished. Subtle and not citable as such in literature, it is a faith that the practices of the scientific world can be so impersonal and trustworthy as virtually to ensure against the perils of human fallibility.

Apparently, during the profession’s first years numbers were seen as pure and their message easily read. Statistical data were regarded as self-identifying as to their relevance and the interpretations to be drawn from them. The literature of perhaps the first quarter century reveals little

Harold F. Breimyer is Professor Emeritus of Agricultural Economics, University of Missouri.

introspective thinking as to what premises or theories necessarily underlie the design of investigatory research or bear on the analytical technique to be applied. It seems incredible that in the 1021 pages of the Taylors' grand *Story of Agricultural Economics* (Henry and Anne Dewees), comments on research method are confined to the briefest of notes on five reports published by the Social Science Research Council. The fragments total scarcely more than a single page (pp. 161, 894, 963–64, 990, 1019–20).

Analytically, during the 1920s the running of averages, frequency distributions, and simple cross-tabulations gave way as the mathematical technique of simple and multiple correlation took the profession by storm. Mordecai Ezekiel's first writing in the *Journal of Farm Economics* appeared in 1923 (pp. 198–213). The *Journal* of the next year carries an article in which Henry Schultz demonstrates the applicability of multiple correlation to a topic that has been copybook for aspiring agricultural economists from that day to this, namely, the demand for beef (pp. 254–78).

The faith that numbers will tell their own story without risk of economists' fallibility was extended to the new technique. It was a shock when Elmer Working pointed out, in a now-classic 1927 article published in the *Quarterly Journal of Economics*, that price-quantity pairings do not even reveal whether a supply or a demand relationship is being described—the identification problem.

Periodically since Working's warning, someone has reminded that there is an element of treachery to the coefficients that correlations produce so readily. In the 1941 and later editions of his price analysis text, Geoffrey Shepherd inveighs against failing to distinguish between correlation and causation (1941, pp. 137–38). A. N. Halter rings the same bell and alleges that economists generally are unclear about causation (1958, p. 1872). In his textbook Shepherd adds a line, almost of apostasy, that “all a correlation coefficient shows is that if the figure is high the relationship is unlikely to be due to chance” (1941, p. 138). As recently as 1988 the correlation-causation issue resurfaced. Thurman and Fisher draw on barnyard examples of the chicken and the egg to treat, half-facetiously, weighty discourses on (alleged) causality in the macroeconomic world (p. 237).

By the time econometric techniques appeared on the scene, the intellectual climate had changed. To be sure, some of the new enthusiasts with

antecedents from early years were quick to pin faith in the miracle-producing power of the new system. But by that time agricultural economists as a genre had become more sophisticated. What followed was a steady flow of exchanges that sometimes dipped into inelegant coinages such as GI–GO (garbage in–garbage out) but more often examined perceptively how numbers-handling or -manipulation is constrained by the precepts of science and the scientific method. A vignette from writings about the econometric era is presented as an epilogue to this review.

In pages that follow will be sketched the principal currents of thought as to the scientific principle in agricultural economics, dating from the profession's earliest years. Sources are primarily the writings in this journal and its predecessors, together with selected other publications.

The Meaning of Science, Place of Theory, and Taxonomy of Research Techniques

The first page of the first issue of the *Journal of Farm Economics* carries an editorial promise that the new publication will “aim to be a seeker for and an expounder of the scientific facts. . . .” In the third issue, published the same year (1919), Richard T. Ely writes of the need for “an agricultural society whose aim is scientific preparation for sound agricultural legislation” (p. 109). Three years later W. J. Spillman, one of the early seminal thinkers, observes that “a science of farm management [lies] hidden in the field” (p. 99). Thus Spillman and Ely, between them, were concerned for science both in managing farms and enacting laws.

But neither they nor their contemporaries addressed the abstract meaning of science. Before long a number of journal writers began to nibble at the edge of the meaning of pure science. E. W. Allen must be credited with being the first contributor to the *Journal of Farm Economics* to take up the cudgel of the meaning of science to agricultural economics. “The aim of science is to discover order, something which occurs with regularity, represents a relationship, or may be expressed in a law. . . . Science assumes order and its task is to discover it” (p. 18).

In 1956 Shepherd dipped briefly into the meaning of science and its bearing on research (pp. 8–14). It remained for Halter in 1958, however, to initiate a roundtable-by-rejoinder (a common pattern) on the topic. Halter found it necessary to begin with the definition of three

words, the first of them science, "meaning that type of mental activity" which satisfies the conditions of "orderly or systematic thinking" and "a definite subject-matter" (p. 1871). Two years later Halter wrote again, incurring Back's rejection of what he sees as Halter's "purely mechanical theory of human conduct" (1960, p. 1474); whereupon Conklin contends that agricultural economists have overly "abstracted from flesh and blood men" and have done so as they "idolized Newtonian mechanical concepts as the acme of science. . . ." He calls "the Newtonian mechanical image . . . unrealistic . . ." (1960, p. 1475).

Halter and Jack take up the subject later (1961), and Back once again offers a discouraging judgment that "none of the particular philosophies of science currently in existence is sufficient as a philosophical guide to research in all the problems of agricultural economics" (1961, p. 908). Kelso reverts when he oversimplifies, saying, "The essence of science is predictability" (1967, p. 224).

Meanwhile, John Brewster, who came to be known as the leading philosopher among economists, wrote and taught about the ancient and modern meaning of science. In lectures at the Graduate School of the U.S. Department of Agriculture, published in part in *A Philosopher Among Economists*, he began with a put-down. In a line paraphrased from the author's memory he said, "I don't want to descend into the snake-pit of what constitutes science." In reality, in his writings he does not dissent from general statements such as that of Allen cited above. His objection is more nearly a corroboration of Back's denial of the usefulness of philosophies of science. Targeting the "body of logic—principles of valid reasoning" that was so popular about mid-century, Brewster insists that much of what we need to know "simply cannot be caught up in any system of logic" (taken from author's notes). He doubts that scientific acquisition of knowledge can be highly systematic.

The subject is reintroduced in literature in presentations Kenneth Farrell, then AAEA president, scheduled in his 1977 program. Moles addresses "The Creation of 'Truth' . . .," and Hartman, "Economics of Science and as Culture." Both stress the cultural element in economic research. Moles: "Science and in specific social science" is "one of the many subcultures in western culture." Further: "Culture may be defined as human knowledge" (p. 919). Knowledge, in turn, is reality, seen as arising in hu-

man experience and not in the rote recording of phenomena (p. 920). Hartman: "The historical faith of science is in the ultimacy of a certain kind of natural order and the effectiveness of the scientific method to discover that order. . . . [But] all qualitative dimensions of human experience were [historically] precluded from scientific understanding. . . . Therein lies the problems of an inadequate cultural tradition" (p. 926). In other words, we can do better.

Strangely, few of the scholars who contemplate the meaning of science take particular note of the necessary process of abstraction. Not many point out that the scientific method inevitably involves abstracting from the complicated universe, reducing it to a scale human beings can deal with. Moles touches on this, as he writes that "any social science approach is used like all other knowledge systems to reduce the complexity of the environment" (p. 921). Breimyer, contributing appropriately to a volume dedicated to Geoffrey Shepherd, more specifically remarks on the abstractions that researchers employ—he calls them "the images of the universe to which agricultural economists address themselves" (1982, p. 57).

It would be hyperbole to credit agricultural economists with having conceptualized the esoteric notion of science and the scientific principle. But it would be inaccurate to the point of disloyalty to fail to acknowledge that agricultural economists have come a long way in achieving an astuteness of understanding of the scientific process to which they give their allegiance.

The Place of Theory in Research

Swanson in 1960 offers salient comments on the scientific concept, but even more pertinent is his interpretation of the relationship of theory to investigation. (Investigation is the original term, eventually replaced by research.) One assumes a theory, he writes, and goes from it to "observations instead of vice versa . . ." (p. 1484). This counsel may now seem axiomatic, but early agricultural economists not only saw no need for theory but were skeptical of theoretical formulations. Bushrod Allin quotes an unidentified outlook economist attending USDA's annual outlook conference, who declared, "We do not engage in theoretical research, ours is the job of analyzing the facts . . ." (p. 409). Even earlier (1940) Theodore Schultz writes that "there are

those among us" (otherwise unidentified) who are alarmed by any mention of "theoretical" and are "filled with sophisticated doubts about that lowly species known as the fact-finding empiricists . . ." (p. 60).

Historically, in 1921 Theodore Macklin recognized a need for an "understanding of the economic forces which underlie the production, marketing and consumption of farm products" (p. 41). E. W. Allen in 1926, however, apparently was the first journal writer to defend categorically the primacy of theory over fact-gathering. His strong language may be appropriate to university courses in research methods today.

My thesis is that a constructive purpose is essential to research; that without it there can be no real research. It is the central idea underlying the method of science, determining all else—the means of approach, the data to be secured, the course of procedure . . . (p. 16).

It is true that science progresses by the determination of facts. . . . But isolated facts, however numerous, do not constitute science. To cite the familiar quotation from Poincaré: "Science is built up with facts as a house is with stones, but a collection of facts is no more science than a heap of stones is a house." And similarly, the indiscriminate accumulation of facts without regard to any central idea or relationship is not in the category of research (p. 17).

Subsequent literature is sprinkled with refinements, such as distinctions between hypothesis and theory. Salter in 1942, after joining others in deploring the practice of compiling "stacks of tables, graphs and maps only to ponder over them unfruitfully," declares forcefully that "hypotheses are a necessary condition to the sorting of facts . . ." (p. 238).

Halter in 1958 chooses to emphasize "presupposition," which "refers to the context in which a true or false proposition is stated." Also, "an absolute presupposition is never subject to the question of truth or falsity as is a proposition" (p. 1871).

In what must be regarded as one of the best journal articles on the role of theory in research, Christensen in 1966 notes that "there has been some misunderstanding . . . regarding the relationship between theory, hypothesis, and model." Some writers, he explains, "would imply that model and theory are one or that hypothesis and theory are the same." He continues, "The hypothesis is a conceptual relationship deduced from the formal theory already established and is a deduction derived from a set of known propositions . . ." (p. 138).

A model, incidentally, is seen by Christensen as "a conceptualization of an abstract system of relationships in terms of something more familiar . . ." (p. 138).

The second stage in the application of theory is to draw on the findings of a research study to revise or refine the preexisting theory. Halter would probably call this the forming of a new proposition. Swanson in 1960 touches on this second stage as well. "Any theory is tentative," he writes, "and subject to further modification with the advent of incompatible evidence. . . ." Moreover, he notes the "integration of probabilistic notions . . ." (p. 1484).

Swanson, however, does not have many companions. It seems surprising that a profession that ploddingly learned to appreciate the place of abstract hypothesis, presupposition, or theory in design of research, has remained less secure in interpreting the findings other than as verification or rejection. There are exceptions. Christensen touches on the second stage, as does Moles. And Halter, as might be expected, offers cogent observations. The scientist, he writes, "realizes that his laws and theories are conjectures and tentative hypotheses and . . . may be rejected as false on the basis of new evidence" (1962, p. 224). Any reformulation comes next. But Halter is one of the few to write in these terms.

Halter almost certainly had picked up Karl Popper's thesis about the falsifiability test, which shows up again in 1989 as Just and Rausser cite Popper's belief in "falsification as the rigorous standard for scientific procedure." They also quote Kuhn, who "found no support" for Popper's thesis. Interestingly, they note without endorsing it that "among economists, McCloskey has advanced the view that economic research is basically essays in persuasion" (p. 1179).

All in all, after three quarters of a century of intrepid research into the economics of agriculture, agricultural economists still show considerable insecurity in the final stage of rejecting or reconstructing received economic theory, or composing a wholly new one.

Taxonomies of Research Technique

Even though they were tentative about articulating the scientific method, the earliest researchers in agricultural economics were quick to develop patterns in research technique. Owing to the profession's obsession with numbers,

during at least the first ten years they gave most of their attention to the collection, analysis, and interpretation of statistical data. Among early concerns were those on how to conduct farm management surveys. Authors wrote about how to make telephonic surveys, for example.

Journal writers have had difficulties of terminology. Those difficulties persist, even complicating the writing of this review article. Economists use the language of research technique, systems of logic and of analysis, philosophy, research tools. Heady refers to the theorist as "tool maker." But he says the agricultural economist is a "tooluser" (1949, p. 837), implying that the agricultural economist does not ordinarily make his own theoretical tools. This viewpoint of Heady is consistent with the first years' engrossment with assembly of data, noted above.

As an arbitrary choice, the more systematic treatments of research technique found in literature will be reported in those terms. There is also a vast literature addressed to method, often mislabeled methodology. It will be noted briefly later.

The philosophy of science and systems of logic show up among the more classically trained agricultural economists, in terms such as induction versus deduction, and positive versus normative science. Conklin in 1947 reminds that "economics originated as a deductive 'science' . . . [consistently with] the Greek belief that all knowledge is derivative of 'pure reason.'" He adds that "inductive methods have come more slowly to economics than to most other branches of academic endeavor" (p. 926). Induction and deduction are rival concepts for Parsons, who sets forth other pairings, such as pure versus applied economics.

Halter, who rarely failed to get into a philosophical fray, refers to "the myth of induction" (1962, p. 223); and he and Jack introduce other terms from Latin and Greek: *a priori* versus *a posteriori*, and analytical versus synthetic. They believe "the key propositions of economic theory should be *a posteriori* synthetic" (p. 95).

Brewster, the acknowledged philosopher of agricultural research, did not fail to remark on deduction and induction in the scientific method. However, he writes that "the hard part of research is . . . discovering a conflict between prevailing theory and exceptional experiences. . . . Deductive development of well-stated hypotheses and testing their probable truth comes in very late stages of our search" (1970, p. 234).

A pairing of concepts that appears occasion-

ally is positive versus normative. In a remark that still surprises, Conklin alleges that "economics began to lose its normative character . . . at the hands of the Mercantilists and the Physiocrats . . ." (1947, p. 926). Inferentially, many early agricultural economists hoped their endeavors could classify as positive, leaving them less subject to challenge in terms of implicit "values."

By any test Glenn Johnson must rank as the foremost thinker in such terms. He elaborates normativism and positivism into pragmatism and variants such as conditional normativism. He writes of "knowledge of values versus prescriptive knowledge" and so on (variously in *Research Methodology for Economists*). In a book reporting a 1985 symposium Tweeten invokes the Johnson credo, dallying with distinctions between normative and positive and then striking comparisons between prescriptive and descriptive (p. 142).

The most structured taxonomies for research technique begin with the monumental study commissioned by the Social Science Research Council referred to above. The report, published in the early year of 1928, touches on virtually all the ideas and terms mentioned thus far in this review: the scientific method (or methods), quantitative versus qualitative, induction versus deduction. The authors classify research technique into five categories: statistical, analogy, case, informal statistical, and experimental.

Leonard Salter, Jr., was a promising young agricultural economist who lost his life in the tragic LaSalle hotel fire in Chicago in June 1946. He still ranks as one of the most systematic thinkers in agricultural economics. In November 1942 he wrote about "cross-sectional and case-grouping procedures" in research, and the taxonomy he set forth in his book, published posthumously in 1948 and reprinted in 1967, features "an outline of inquiry" constituted of problematic situation, formulation of problem, hypothesis, processing of evidence, and a terminal test. The terminal test is as to whether "purposive action is instituted and consonant with consequences" (pp. 68–69). As to research technique (which Salter calls methods), the following are listed: experimental, historical, case, qualitative description, analogical, logical, and statistical (pp. 70–77).

For reasons that are not entirely clear, Salter's field of land economics has lent itself to discourses on research technique in its manifold interpretations. The papers for a symposium, published in a 1966 book edited by W. L. Gib-

son, Jr., R. J. Hildreth, and Gene Wunderlich, essentially captures the thinking of the time.

Several writers have since exhibited their own favorite taxonomies. Alan Randall, addressing resource economics (a successor to land economics in attention getting), reverts to pairings. He recognizes "four major schools of thought" and labels them "institutionalist/land economics; neoclassical/rational planning; public choice/utilitarian; and public choice/individualistic" (1985, p. 1022). Shabman follows by "recasting Randall's schools . . . into two groups: the mainstream, which includes his N/RP, PC/U, and PC/I, and the institutional, or his I/LE." Also, he (Randall) does not "distinguish resource economics from the larger discipline" (p. 1030).

If research technique is the most discretely identifiable structuring of research, ideas surrounding research philosophy are the least so. The term, philosophy, shows up randomly, with the single exception that John Brewster virtually built his career on philosophical concepts. The collection of Brewster's articles, edited by J. Patrick Madden and David E. Brewster, has been noted above. Kenneth Parsons, in 1949, mulls over "what we may call the philosophical frame of reference" (p. 658). Karl Brandt, in 1955, recommends a study of philosophy; and Halter, citing Brandt's faith that it "would lend clarity to our understanding of the nature of economics and to its research methods," adds that "this reference to philosophy has gone unnoticed" (1958, p. 1871). Brewster's star was rising fast at the time, but Halter presumably had not yet taken note of it. As is mentioned above, Halter and Jack later wrote about "a philosophy of science for agricultural economics research." Back entered the fray in 1961, as did a few other economists later. Generally, though, except for the work of Brewster and just a few others, philosophy as orientation to agricultural economics has proved to be almost ephemeral.

The Catch-all of Method—or "Methodology"

A profession that has preferred to minimize the personal and maximize the procedural or instrumental fills its literature with discourses on operating tactics or procedural patterns, usually tagged by the Mother Hubbard term method or, sometimes and erroneously, "methodology."

With regard to the term itself, Don Paarlberg is perhaps the most candid in objecting to methodology, as "this employment of the term is out

of keeping with scientific usage. . . . Most agricultural economists use the word methodology when they are concerned neither with philosophy nor with logic but simply with method. The three syllables are added to convey prestige" (p. 1386).

Frank H. Knight, famed economist of the University of Chicago, told agricultural economists that he finds fault even with addressing method. "I must begin by confessing a degree of skepticism about the practical value of writing on 'method' (a term less pretentious than 'methodology') at a highly abstract level" (p. 112).

But the term method is itself ill defined. Perhaps each method can be viewed as a substratum in a research-technique taxonomy. A great many of the methods that are discussed in literature today relate to the three-century-long preoccupation mentioned at the beginning of this paper, namely, that with numbers.

In a major review published in volume two of *A Survey of Agricultural Economics Literature*, itself anticipated in a 1968 *AJAE* article, George Judge sketches historical works on what he calls estimation in economics. He puts methods of estimation in the category of measurement, and sees "a systematic use of economic and statistical models, methods, and data" as giving "empirical content to economic theory and practice . . ." (p. 3).

As it is questionable whether the prolix and diverse writings about method can be tested against scientific principle, all that will be offered here is a sampling of the practices and conceptualizations that can loosely be called method. Veterans will recognize a number that were prominent briefly. Most of them disappeared. Faddism is not absent in agricultural economics.

It all began with methods of collecting data (the counting era). Next we find a panoply of "statistical methods of analysis" ranging from measures of central tendency to the new simple and multiple correlation, followed by simultaneous equations and other more elaborate forms. The particular equilibrium drew a brief focus of attention and methods were applied to it. In 1953 Fred Waugh, asked to review the applicability of developments in methodology, addressed method instead and listed the following, among others: sampling, design of experiments, consumer panels as data source, structural analysis, economic models generally (they were just coming into popularity), linear programming (due to have a long life), theory of games. In the same

issue of the *Journal*, Richard King introduces activity analysis. Input-output models show up periodically. Marc Nerlove made distributed lags a household word in agricultural economics. The Markov process has been popular intermittently, as has simulation. Dynamic programming, control theory, gini ratios, and a host of other terms and coinages dot the writings in agricultural economics. Some are of lasting merit, others a passing fancy.

In a book reporting a 1985 symposium (published in 1988), Glenn Johnson and Stanley Johnson present a comprehensive inventory of the methods currently at agricultural economists' disposal. Glenn Johnson calls his list technological innovations, and Stanley specifically names quantitative techniques. A discussant, David Bessler, says Stanley surveys "virtually all interesting (useful) techniques in use today" (p. 199).

The Judge inventory of methods in estimation is another useful compendium (1977).

The almost countless designs for conceiving and carrying out agricultural economic inquiries, primarily quantitative in nature and commonly classified under the general term method, are a part of the profession's fabric and yet are peripheral to the most signal tenets of the scientific principle. For this reason they are given only this serial mention.

On Behaving as a Scientist

It ought to have been evident even to the first economists who called themselves agricultural that it is not possible, or even desirable, to carry out agricultural economic studies so impersonally as to neutralize the human factor—converting, in Conklin's language, the investigators into mechanics (1960, p. 1475). The role of the scientist is endemic to all scientific inquiry. As recently as 1989, when the prestigious National Academy of Sciences commissioned a thought-piece on "the nature of scientific research" the opening question, "Is there a scientific method?" was answered in terms that match the thesis of this review, that dedication to scientific principle does not lead to a singular system of scientific practice. It is significant that the resulting publication carries the title, *On Being a Scientist*.

Throughout the history of science, some philosophers and scientists have sought to describe a single systematic method that can be used to generate sci-

entific knowledge. For instance, one school of thought, dating back at least to Francis Bacon . . . , points to observations as the fundamental source of scientific knowledge. . . . By gathering facts without prejudice, a scientist will eventually arrive at the correct theory.

Some scientists may believe in such a picture of themselves and their work, but carrying this approach into practice is impossible. . . . Scientists may be able to suspend some prior theoretical or thematic preconceptions . . . but they cannot view the physical world without any perspective. (p. 2)

In spite of the futility of denying the scientist's role, in the early literature of agricultural economics that element in research is rarely mentioned. Halcrow and Brinegar forthrightly put into words a silently professed thesis of the early years: "Retgression in scientific analysis occurs when allegiance is pledged to men rather than to impersonal processes" (p. 122).

As was predictable, questions of the human factor and economists' performance could not be muffled indefinitely. The moral quality and technical competence of the "men" in agricultural economics drew the attention of a growing number of these individuals.

Interesting and perhaps surprising is Theodore Schultz's quotation from John Maynard Keynes as to the qualities of an economist, who "must reach a high standard in several different directions and must combine talents not often found together." He must be catholic and also "purposeful" but also "disinterested in a simultaneous mood, and as aloof and incorruptible as an artist . . ." (p. 60).

As noted above, Glenn Johnson (in various occasional papers and *Research Methodology for Economists*) led a sizable cadre that matched subjective against positive and introduced terms such as normative and conditionally normative. These relate not so much to impersonal technique as to the role of the human being who collects and examines the data and tries to draw conclusions from them. Manifestly, in this context the researcher is no longer seen as innocuously neutral. Members of the profession listened to Johnson respectfully but did not always confine themselves to his terminology.

Values, Objectivity, Morality, Ethics

Viewing scientific performance in terms not of a formal impersonal system but of the conduct of the scientist opens up questions that the early agricultural economists wanted strenuously to

avoid and that continue to be unattractive to some members of the profession. It suggests that science and practices under its banner are partly a matter of the individual scientist's stance—his outlook, his *Weltanschauung*. A number of agricultural economists have been not only aware of this opposite side of science's coin but have pondered it and written about it. Again, the reference points have varied but have embraced concern for values, objectivity, morality, ethics.

The historical record shows several episodes of preoccupation with values. In 1949 Parsons touched on "the value problem in economic behavior" (p. 679). Frank Knight, reviewing Parsons, writes of "the ambiguous nature and true role of values" (p. 120). He sees two meanings to the word, value. "When used in economic theory, this term refers only to individual or subjective desire, as expressed in choice among alternatives presented" (p. 120). "In contrast," though, "economic policy, and all discussion of any common policy, inevitably refers to . . . some kind of 'objectivity,' some degree of right-and-wrong, capable of being argued." Further, "It involves a distinction between desire and choice as facts versus what they ought to be . . ." (p. 120).

In 1961 Earl Heady as director of the Center for Agricultural and Economic Adjustment at Iowa State University doubtless was instrumental in staging a seminar at that university on "Goals and Values in Agricultural Policy." The papers comprise a book bearing the title.

Many agricultural economists remained diffident about the idea of values, apparently satisfied with vague notions of cultural influences on a researcher. But in 1954 L. John Kutish demonstrated that "the value question" could generate the heat of spirited exchange.

Brewster, as would be expected, touched on values frequently: in "The Cultural Crisis of our Time" (*A Philosopher Among Economists*, pp. 7–65); in "Society Values and Goals in Respect to Agriculture" (*Goals and Values in Agricultural Policy*, pp. 114–37); and in "Beliefs, Values, and Economic Development" (*Journal of Farm Economics*, November 1961).

In all his writings Brewster rarely bothered to define the term, value. He regarded values, redundantly, as "judgments as to what is valuable," and he had society's judgments in mind (p. 158). He implicitly expected the agricultural economist as scientist to accept and be faithful to society's values, and not substitute his own.

Values remain a part of the vocabulary of agricultural economics, but the word has given way

before a related concept that may entail even more sensitive responses, that of objectivity. As Heady suggests, objectivity itself can be regarded as a value; in a seeming contradiction, it adjures the value-steeped economist not only to set aside his values (other than possibly the most elevated ones) as he addresses economic issues, but also to resist all enticements to bias or adulteration.

It may be supposed that agricultural economists generally subscribe, if only subliminally, to the principle of objectivity, yet are not eager for questions to be raised. In 1950 the ever-stimulating Frank Knight, not one of the clan, called attention to the principle in relation to "fact" and "generalization" (p. 113). "Nature," he writes with more than a little whimsy, "is 'honest.'" But "in human conduct" it is necessary to allow for unpredictability as "affected by *error* [his italics]," in several meanings, and by ignorance and prejudice; and where social relations are involved, "outright deception is a fundamental fact" (p. 114).

Harsh language.

When Breimyer in 1967 opened up the subject, he was more guarded or even gentle as he presented his stand that "if agricultural economics is to be a science . . . the precepts of scientific objectivity must be adhered to" (p. 340). He then diplomatically suggests that "the most persistent of all blocks to the objectivity test . . . [may be] the human tendency to avoid areas of controversy . . ." (p. 347). Even so, he does not fail to note "the most recent of all threats . . . [which] arises when an economist divides his time and allegiance so as to multiply his income" (p. 348). And he leaves no doubt that in his mind the test of objectivity must be met if agricultural economics is to "wear the esteemed toga of a science" (p. 350).

Whether the Breimyer literary fist was gloved or mailed, it incited responses. Grove rebuts that "most agricultural economists pretend to an objectivity they do not possess" (p. 153), and the only recourse is subjective dissent (p. 155). Schmitt and Timmerman concur in the judgment of nonattainability of objectivity (p. 921).

Castle, in another follow-up, admits that objectivity is hard to come by and lists a number of threats to it including desire for approval (pp. 810–11).

Alan Randall, the next economist to consider the behavioral paradigm of the scientist, examines "the moral responsibilities of the scientist and his host institution. . . ." He "explicitly acknowledges the role of power in economic interaction." The scientist and his in-

stitution are confronted with "the necessity of making distinct moral choices . . ." (1974, p. 227).

If Randall in 1974 selected the language of morality, in 1983 Maurice Kelso chose yet another variation on the theme as he set up at the AAEA annual meeting a session on "Ethical Issues in Resource Economics" (cf., e.g., the discussion papers by Glenn Johnson and Raymond Anderson).

And so, during forty years of journal exchanges among some of the leading lights in agricultural economics, the bearing of economists' behavior patterns on the scientific quality of the profession's output is examined in variable language but with consistent purpose. And in 1989 Just and Rausser reintroduce Heady's original term of objectivity. They call "insistence on objectivity . . . one of the dominant characteristics of the profession." As did Grove twenty-one years earlier, they see the best protection "in the clash of individual subjectivities" (p. 1179). Only if some individuals are objective and declare themselves can the majority be expected to be so.

The Unsystematic or Uncodified Component to Investigations in Agricultural Economics

In a striking contrast, agricultural economists' testimonials to science and formal scientific practice are mixed with occasional enjoinders to the opposite. Surely, systematic rigor is to be extolled and even mandated. But there is a place also for imagination, inspiration, even perhaps for day-dreaming; and for anecdotal evidence. A number of writers have so declared, sometimes insistently.

Swanson senses the place of intuition. "It is tempting to speculate on the future of the relative emphasis within our profession on the role of the informal predicting expert who uses judgment, intuition and wisdom and that of the researcher methodically seeking to explain phenomena" (p. 1485).

George Ladd carries the argument further, in trenchant language. "We pay little attention . . . to the research tools that are the most versatile and frequently used of all . . . [namely] subconscious mental processes (imagination, intuition, hunch), chance (including serendipity), and writing" (1979, p. 1). In his book, *Imagination in Research*, he explains further that "we need imagination to provide the insights leading to theories that fit the facts. And we rely on in-

tuition for the postulates that support our rules of logic" (p. 134). Ladd even goes so far as to note a place for doubt and tension as contributing to imagination for research.

Brewster, nevertheless, ranks as the foremost exponent of the unsystematic ingredient to research that may otherwise class as scientific:

"Yet . . . there is much to the research quest . . . that cannot be reduced to systematic rules of right reasoning. No rule can be given that will induce one to perceive conflicts between prevailing generalizations and exceptional observations . . . [and] will lead one to induce . . . new hypotheses. . . . In this important sense, research includes far more than mere logic, whether deductive or inductive. It includes insight, genius, groping, pondering—"sense" which can't be boxed up in any formalized procedures. The logic we can teach; the art we cannot . . . (1970, pp. 234–35).

An Epilogue: The Game of Lambasting and Defending Mathematics and Model-building

For longer than a generation, agricultural economists have sparred over what its critics regard as an obsession with mathematics and the constructing of models, often intricate ones. Most of the exchanges have been good-spirited. There is substance to the debates, and a sampling is presented here.

This feature of the historical record is nevertheless presented as an addendum or epilogue because it is not fundamental to an account of the place of science and the scientific principle in agricultural economics.

Most of the verbal tussling has related to the third of the three stages of agricultural economics' preoccupation with numbers, that is, econometrics. During the years of counting, the lightest touch was to admonish field surveyors to phrase their questions carefully. "If the farmer can't answer, look to how you ask the question!"

A few ripostes followed the introduction of the exciting new correlation techniques. Don Paarlberg, for example, says we went crazy and "correlated everything with everything else . . ." (p. 1390).

The early beginning of arguments about the place of mathematics in agricultural economics is attested to by Thompson's pooh-poohing them (1937). "Those who make too strong a claim for the mathematical method appear to believe that this method can of itself yield valid conclusions

. . .” Not so: “there is no *logical* difference between reasoning without mathematics and that which uses higher mathematics. . . .” Then a pox on the other house: “The opposite view that the mathematical method is completely useless for economics usually rests on the mistaken identification of this method with measurement” (p. 718).

Arguments waxed warmer as research moved more fully into econometrics with all its intricate wizardry. In 1961 Karl Fox set up, at the winter association meeting, a session on “Contribution of Econometrics to Farm Price and Income Policy.” Breimyer in a discussion paper offers a judgment consistent with Thompson many years before, one that also anticipates the barrage of evaluations that fill the journals of recent years. “In the magic of electronics the limiting factor is not capacity of computation but expertness of programming. Moreover, neither the electronic machines nor mathematical concepts can compensate for any deficiency in underlying economic theory and understanding . . .” (p. 383).

Paarlberg in 1963 calls it a delusion to think “that the new methods, being mathematical, shelter us from the hazards of human judgment . . .” (p. 1390). Two years later Norris Pritchard pleads for recognizing the limitations of mathematical methods (pp. 152–53). Thereupon Hildreth was moved to ask, at the 1965 annual meeting, “Have we gone too far?” He cites (pp. 1497–98) Paarlberg’s further warning that “no method can produce rational results from erroneous data” (p. 1390) and Kelso’s harsher charge that “the elegance, the tidiness” surrounding mathematical models may only lead us to be “wrong in a more elegant manner” (1965, p. 11). For balance he quotes Waugh’s judgment that “sophisticated techniques are necessary to analyze difficult problems in our complex world” (1964, p. 866). And Heady: quantitative tools have greatly improved the agricultural economist’s ability to handle the masses of data necessary for analysis (1963, pp. 120–22).

In the February 1972 issue of the *Journal*, Oscar Burt and William Martin exchange barbs that are germane to the adequacy-of-data versus ingeniousness-of-technique dispute. Burt had written an article on the economics of investment in specified range improvements. In *Journal* pages the two economists combat as Burt defends his adapting a dynamic programming model to data of acknowledged shortcomings, leading Martin to charge that the exercise amounts

to redefining a problem to fit “the specifications of the tool.” “Elegance,” he added (Kelso’s word again), “is the medium . . .” and has become the message (p. 134). Burt then alleges that Martin confuses “elegance with rigor” (p. 135).

Has much changed since George Warren sought to get better data to put into the farm management studies then being developed? Perhaps not. Warren, however, did not pretend to elegance.

The issue has stayed joined since Warren’s day, yet an emerging consensus may be sensed. If so, it is likely to be consistent with Hildreth’s judgment in 1965 that we have not gone too far in quantitative dexterity (p. 1501) and the real need is “for better training in economics and methodology . . .” (p. 1503).

A consensus judgment may be that employment of mathematical methods does not substitute for rigorous theoretical formulations in agricultural economics. Rather, it itself requires more precise understanding of the constructs of which the discipline is constituted.

Inasmuch as rhetorical exchanges among agricultural economists tend to be cyclical, a new outpouring of challenge and response on the practices attending the econometric stage in agricultural economics can be anticipated in years to come.

All of which introduces a jingle Frederick Waugh attributes to Herman Southworth (1953, p. 706):

Our economic methodology
is full of fine epistemology.
But when we come to problems practical
our theories are too didactical.
If economics is a science,
it needs to foster the alliance
of theorist and statistician,
with manager and prognostician;
To tie the work of mathematicist
to problems of the market strategist.

Rent Seeking: The Potash Dispute between Canada and the United States

Valerie J. Picketts, Andrew Schmitz, and Troy G. Schmitz

Despite the Canada-United States Free Trade Agreement, border disputes involving agricultural trade are common. A theoretical basis for the 1987 U.S. countervailing duty case against Canadian exports of potash is developed using excess capacity arguments. Empirically, within a rent-seeking context, the U.S. potash producers gained far less from their legal action against Canada than did U.S. farmers who are significant users of Canadian potash.

Key words: agricultural trade, countervailing duties, potash, producer rents, rent seeking, user rents.

Border disputes involving trade in agricultural inputs between Canada and the United States have received relatively little attention in the economic literature even though the problem is of major significance. Charges of export dumping continue despite the signing of the Canada-United States Free Trade Agreement. This paper focuses on countervailing duty actions against Canadian exporters of potash to the United States, which is a major user. Potash production in Canada is a multimillion dollar business as it is both the major supplier of potash to the U.S. market and the largest exporter of potash in the world.

The structure of the potash industry in North America is oligopolistic because of the existence of a few players and the ability of the larger firms to affect prices (Anderson, Bennett, Fulton and Schmitz, Olewiler, Flatters and Olewiler). Two such firms are the International Mineral and Chemical Corporation (IMCC) and the Potash Corporation of Saskatchewan (PCS), which control almost half of the potash production in North America. The largest player in the North American potash market is Canada, where

Saskatchewan accounts for approximately 95% of Canadian production and New Brunswick produces the other 5%.¹ Canadian production accounts for approximately three-quarters of North American production (Korol, p. 6). Potash is sold both to the United States and in offshore markets. Canpotex, Ltd., sells all of the exports of the Saskatchewan potash producers to the offshore market.² In contrast, each of the several Saskatchewan producers market potash independently in the U.S. market. Approximately two-thirds of Saskatchewan production is sold to the U.S. market, and the remaining one-third is sold offshore (Korol, p. 9).

Most of the 1970s and early 1980s were prosperous times for the potash industry in North America, largely because of high grain prices and high farm incomes. However, the potash market changed quickly as a result of falling grain prices; and, by the middle of the 1980s, potash producers in North America had experienced substantial losses. This prompted two American potash producing firms in 1987 to sue the Canadian potash producers for dumping potash on

Valerie J. Picketts is livestock market analyst at the Economics Branch, Saskatchewan Agriculture and Food; Andrew Schmitz is chairman and a professor, Department of Agricultural and Resource Economics, University of California, Berkeley; Troy Schmitz is a research assistant, Department of Agricultural and Resource Economics, University of California, Berkeley.

The authors thank the three anonymous referees and Casey Van Kooten for insightful comments.

¹ Saskatchewan produces muriate of potash (potassium chloride), which is one form of potash. Over 95% of North American production is muriate of potash, and it is considered a homogenous good. Approximately 95% of the muriate of potash produced in North America is used as fertilizer, and there is no substitute for it in the agricultural market (Korol, p. 6). Muriate of potash is generally not used on Canadian soils; therefore, U.S. farmers are the major consumers of Canadian potash in North America.

² New Brunswick opted to stay out of Canpotex, Ltd., which is a company that sells Saskatchewan potash offshore.

the U.S. market (Bowley). Countervailing duties were then placed on Canadian potash exports entering the United States. Subsequently, the Canadian potash firms increased their prices; in response, the duties were lifted on Canadian potash.

The legal action of the U.S. potash firms can be viewed as rent seeking along the lines presented in an earlier paper by Bredahl, Schmitz, and Hillman on the tomato war between the United States and Mexico. An intensive campaign was launched by U.S. potash producers in lobbying the U.S. government into imposing duties on potash imports (Marud). The duties created economic rents for the U.S. potash producers by increasing the price received. However, U.S. farmers lost rents as a result of the price increase. They attempted to prevent the imposition of the duties but failed. In contrast, Canada incurred a net gain in rents resulting from the price increase.

The potash dumping case is interesting because it appears that rent seeking on the part of U.S. potash firms created sizable gains for Canada at the expense of U.S. farmers. Often, in agricultural border disputes, the opposite is the case. Producers of commodities bring antidumping charges against exporters because dumping behavior depresses commodity prices. The action by U.S. potash producers essentially stopped the Canadian potash producers from pricing below the cost of production (Greenaway). The increase in price caused profits to increase for potash producers in both the United States and Canada. The legal action by the U.S. government, in essence, created a cooperative pricing solution where the rents of both parties increased.

The overall objective of this paper is to formulate a model for analyzing countervailing duties in a mineral market such as potash. The empirical objectives of this paper are to estimate (a) the effects on both Canadian and U.S. potash producers and on U.S. farmers from the implementation of the potash duties in 1987; (b) the rents under two different assumptions on pricing behavior by Canadian producers, namely, (i) dominant market strategy and (ii) competitive market strategy. The rents estimated in (a) above are then compared to the rents generated under the dominant and competitive strategies.

In earlier literature, dumping is defined as price discrimination between national markets. It is thus treated as profit maximization by a discriminating monopolist or as an oligopolistic tactic to eliminate competition or to enforce a cartel.

However, in this paper, we use the modern approach to dumping, where adjustment costs and excess capacity are considered (Ethier). Dumping occurred in the potash industry largely because of excess industry capacity created by falling demand. In this connection, dumping was determined on the basis of "fair market price." This method is often used in antidumping disputes (Schmitz, Firsch, and Hillman). Concerning dumping in raw materials such as potash, Lloyd noted earlier that dumping is particularly likely in industries where there is surplus capacity, either because of cyclical reduction in demand or because of irregular investment patterns in large plants.

The Potash Trade Dispute between Canada and the United States

In 1982, low grain prices and high real interest rates caused potash demand to fall. This led to a large decrease in the production of potash in Canada (Fulton and Schmitz, p. 32). However, U.S. potash production increased because of the production cutback by Saskatchewan producers in their attempt to maintain prices. Despite the cutback, the price fell from \$146 in 1981 to \$109 in 1982 (U.S. dollars per metric ton of potassium oxide; unless stated otherwise, all dollars are in U.S. currency). In 1983 and 1984, potash demand recovered to near previous levels, and Saskatchewan producers appeared to switch to a competitive strategy by decreasing prices in order to gain market share. This resulted in a considerable drop in price, and the Saskatchewan producers' market share and capacity utilization rate increased during 1983 and 1984. In 1983 the consumption increased but the price fell from the 1982 level by an additional \$13 per metric ton. The Canadian market share increased from 82% of agricultural sales in 1982 to 89% in 1984. In 1985 and 1986, the price fell further as a result of a competitive strategy of increasing market share at the expense of price (Korol, pp. 34, 35).

On 10 February 1987, two American firms (Lundberg Industries of Dallas, Texas, and New Mexico Potash Corporation of Memphis, Tennessee) filed a lawsuit against several Canadian producers for dumping potash in the United States at prices which were alleged to be 43% below the cost of production. In 1987 these two firms accounted for less than 15% of the potash consumed in the United States. The suit was filed through the U.S. Department of Commerce and

the U.S. International Trade Commission. The American potash companies perceived that the Canadian producers were price cutting to increase their market share in the United States; the Canadian market share of agricultural sales increased from 82% in 1982 to 88% in 1987 (U.S. Department of Interior). The International Trade Commission agreed on 3 April 1987, that there was indication of "unfair price discrimination"; and on 21 August 1987, the United States announced the preliminary duties on Canadian potash.

The Provincial Government of Saskatchewan responded by limiting potash production in order to increase the world price of potash. If the Saskatchewan potash producers exceeded their production limits, they faced a fine of \$1 million by the provincial government. If they continued to produce after the limit was exceeded, then the fine would be \$50,000 per day. In September 1987, PCS announced that it was increasing its price by 60%—from \$58 to \$93 per metric ton—with the expectation that the other Saskatchewan producers would follow its lead. Following the lead of PCS were IMCC; Kalium Chemicals; Cominco, Ltd.; and Noranda, Inc. Therefore, PCS successfully acted as a price leader.

The U.S. farmers who stood to lose from the rent seeking of the U.S. potash producers lobbied the U.S. government through organizations such as the National Corn Growers Association. However, the farmers' lobbying was unsuccessful.

In December 1987, the Saskatchewan producers agreed to stop this dumping behavior. As a result, on 8 January 1988, the Canada-U.S. dispute case was suspended for five years by an agreement between the Saskatchewan producers and the U.S. Department of Commerce. The duties on potash were to be removed as long as Saskatchewan firms did not sell their product to U.S. producers below the "minimum price" calculated in accordance with the agreement within the five-year period. The agreement defined the "minimum price" for each producer as the price not less than a price equal to the current "fair value" of its potash minus 15% of its preliminary dumping margin. The current "fair value" of potash for a producer would be either: (a) the constructed value of its potash if it was selling below the cost of production, (b) its Canadian price if it had 5% or more of total sales in Canada and if its price was above its production costs, or (c) its offshore price if it was selling at prices above its cost of production but had an insuf-

ficient volume of sales in Canada. On 25 January 1988, PCS announced that it would decrease its price by 15% of its dumping margin value according to the fair market value definition.

The Model

The potash market is depicted in figure 1. The marginal cost curves are constant over a wide range of production until the capacity constraint is reached, at which point they increase sharply (Bennett, Korol). Also, production costs in the United States are significantly higher than in Canada (Energy, Mines and Resources). In figure 1, the marginal cost curves for Canada and the United States are S^cbs^c and S^us , respectively. These reflect the cost differences between the two countries including transportation costs. They also show that the capacity level of the U.S. firms is relatively small compared to the Canadian firms. The aggregate supply schedule is S^cbedS^* , the demand for Canadian potash in the offshore markets is D_{os} , the demand from the U.S. market is D_{us} , and the sum of the two demands is represented by TD . There is no significant Canadian demand for potash. Hence, a demand schedule for Canada is not drawn. At price P_s , aggregate output is Q_2 , of which Q_1Q_2 is shipped offshore. U.S. output is Q^u , and Canadian output is Q_1 . At the competitive equilibrium price P_s , firms in the United States earn rents equal to the cross-hatched area $ac'de$, while Canadian firms earn rents totaling P_sabS^c . In this model, rents are positive for firms in both countries because aggregate demand TD lies to the right of the capacity constraint demand TD' . Thus, sizable rents can exist even in the absence of some form of cooperative pricing strategy among firms.

If the U.S. and Canadian firms were able to cartelize, the industry output would be restricted and profits would increase. One such example of cooperation would be dominant firm pricing strategy by Canada. Canadian output would be restricted to Q^* , price would increase to P^* , and U.S. output would be unchanged. In this case the largest percentage of profits from cooperation would go to the United States (profits increase by $gfc'a$) along with an increase in the U.S. market share. There is also an optimal import-export cartel pricing solution, different from the above, where market shares between the United States and Canada could remain virtually unchanged. This solution was derived by Bre-

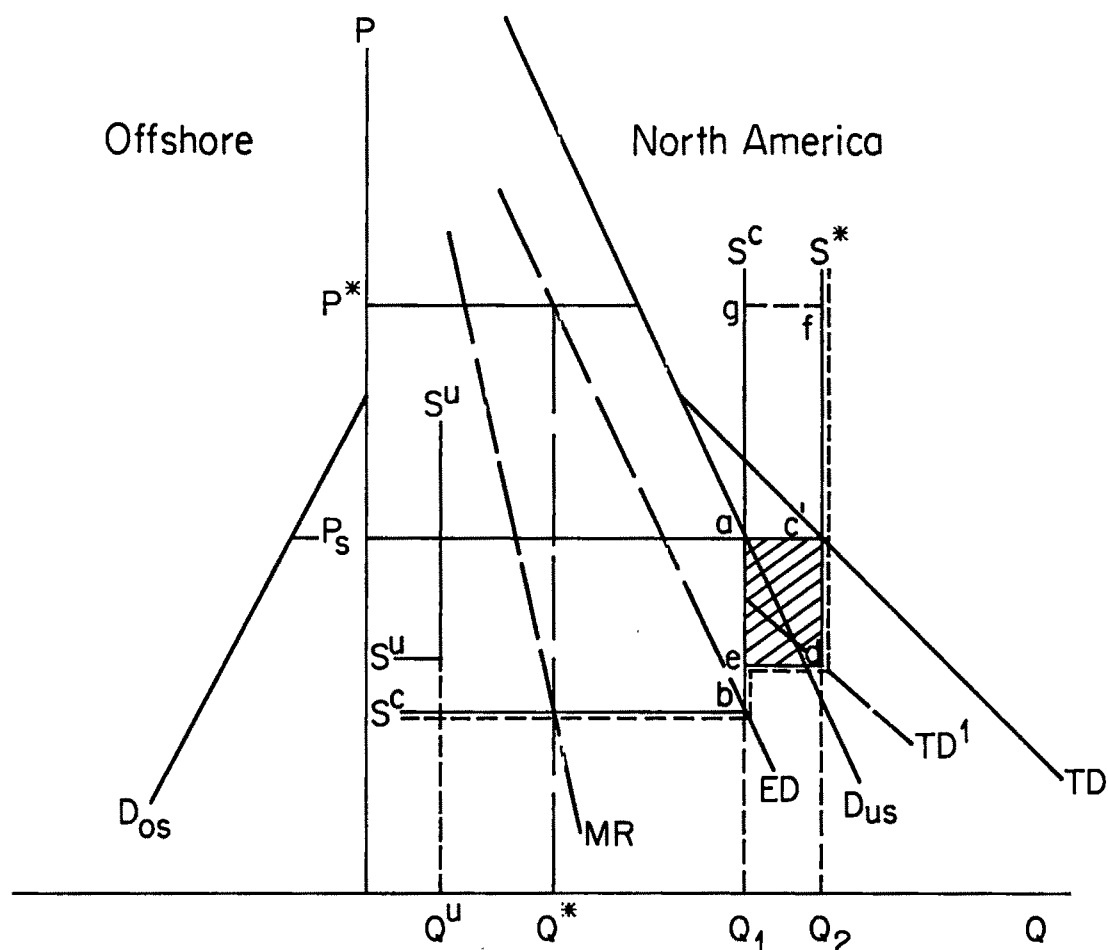

Figure 1. Price equilibrium and dominant firm pricing

dahl, Schmitz, and Hillman in their discussion of the tomato war between the United States and Mexico.

The U.S. dumping litigation against Canadian firms has been assumed away in figure 1 because it does not allow for industry losses. Often the potash industry has excess capacity and loses money (negative rents). The negative rent model in figure 2 depicts the case that existed prior to the introduction of the U.S. dumping lawsuit in 1987. $S^u S^c$ represents the U.S. supply curve, and $S^c S^c$ represents the supply schedule for Canadian firms. Total supply is given by the $S^* d a e S^c$. Given total demand TD , aggregate output is Q_2 at price P_s .

Suppose aggregate demand shifts to TD' . If both countries continue to produce aggregate output Q_2 , both suffer losses. The loss to Canadian firms is $P_1 b e S^c$, while the loss suffered by U.S. firms is $a d f b$. The combined loss is the

cross-hatched area $S^c e a d f P_1$. Note, however, that the U.S. users of potash gain from these over-production activities.

The model in figure 2, where price is P_1 and Canadian output is Q_1 , is clearly a classic dumping case viewed from the standpoint of U.S. potash producers since Canada is selling to the U.S. market below the cost of production. What if the United States is successful in imposing a duty of T , requiring Canada to price at P_0 if they want the U.S. to remove the duty? It is in the best interest of Canadian firms to cooperate and price at P_s in order for the United States to remove its duties with the result that the Canadian firms no longer lose money. However, in equilibrium, if the U.S. firms are not willing to cut output, Canadian firms have excess capacity of the amount $a a'$. Thus, they will have to cut output to Q^* but in so doing will lose market share.

Even with the cutback in Canadian production

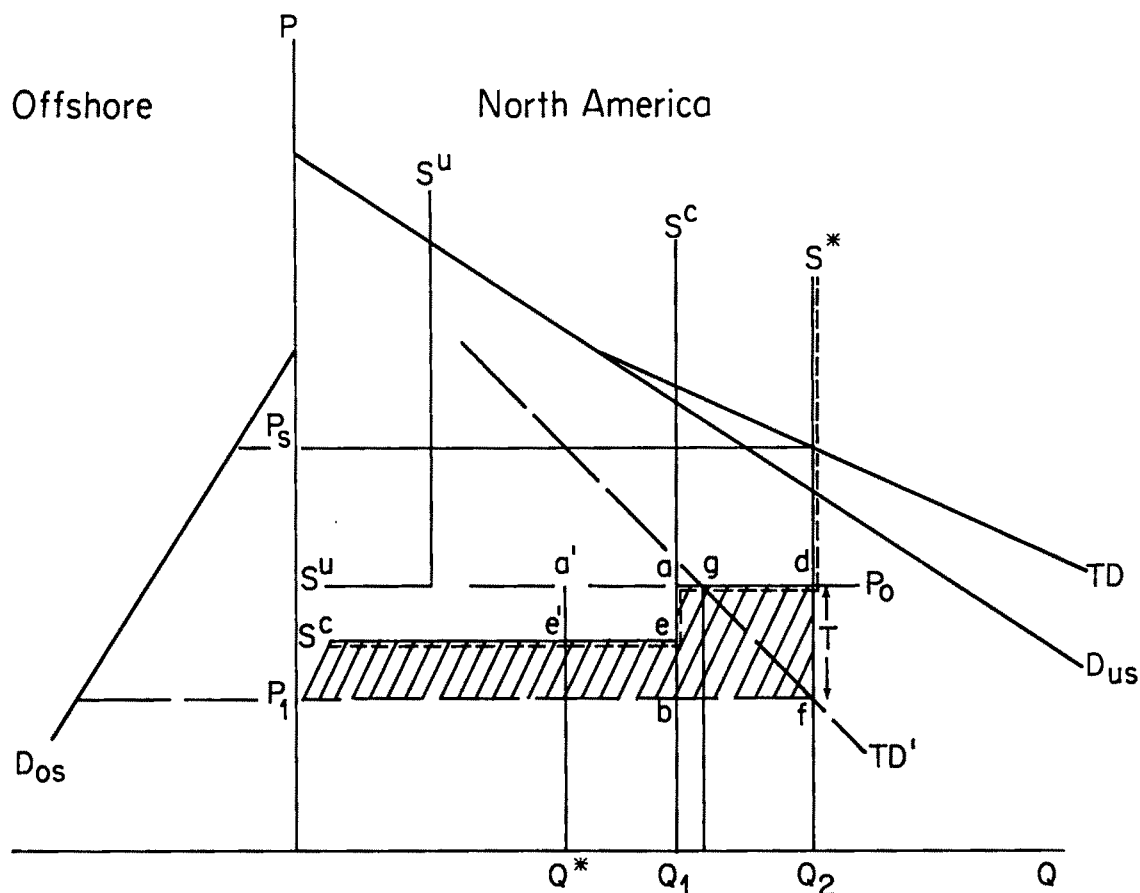

Figure 2. Negative rents in the potash market

to Q^* , there are also gains to Canadian firms. These firms now have positive rents of $S^u a' e' S^c$. However, U.S. potash users lose $S^u g f P_1$. Interestingly, both the U.S. and Canadian industries gain from the temporary duty T if these duties result in a permanent price of P_0 (at which time they can be removed). However, the loss to U.S. potash users is greater than the gain to U.S. potash producers. Clearly, the dumping suit was against the best interest of U.S. corn producers.³

In the model by Bredahl, Schmitz, and Hillman on rent seeking, attempts on the part of U.S. tomato growers at imposing tariffs were viewed as a competitive strategy because, if imposed, the rents to Florida producers would increase while rents to Mexican producers would de-

crease. This, however, assumes that the tariff would be permanent. In the potash case this was not so, as the exporters agreed to raise the price so the tariff could be removed. As a result, the dumping charge by the U.S. producers ended by having the U.S. and Canadian firms cooperating, whereby rents to both were increased as a result of the imposition of duties. However, market share was lost by Canadian firms. A more optimal solution for Canada was clearly one where both the United States and Canada reduced output. Regardless, rent-seeking activities on the part of the U.S. potash producers to persuade Washington to impose temporary duties were, as shown later, costly to U.S. farmers; also, U.S. potash producers gained less than users lost.

Antidumping behavior changes the mean price of fertilizer purchased by U.S. farmers. If demand fluctuates between TD' and TD (figure 2), farmers would pay prices ranging between P and P_s . However, with the threat of antidumping ac-

³ Because of the cost differences between the United States and Canada, if the U.S. insists that Canada does not price below P_0 (using as a threat the reintroduction of countervailing duties), Canadian firms are always guaranteed a positive rent because price exceeds marginal cost.

tivity, farmers pay prices ranging between P_0 and P_s . As a result, the mean price of fertilizer facing U.S. farmers increases.

It appears that a U.S. lawsuit was necessary to change the pricing and production strategy of Canadian producers. Why this apparent irrational behavior by Canadian firms prior to the antidumping litigation? There are several explanations: (a) Canadian potash producers might have expected that potash demand would be weak for only a short period of time (in this case, a strategy of shutting down and reopening several potash mines may have been viewed to be a more costly alternative than that which was actually followed); (b) the producers might not have perceived the magnitude of the demand shifts; (c) there may have been predatory pricing behavior by one or two of the potash corporations within the Canadian complex; and (d) for many potash firms, it is difficult to cut back production drastically in a short period of time. (Ethier). To do this requires substantial layoffs. This is politically unacceptable, especially for PCS which, at the time of the countervailing duty action, was entirely a Crown Corporation. Worker layoffs could be justified much more easily as a response to countervailing duty action.

Regardless of the reasons, the Canadian potash industry was unable to cut back production to raise prices significantly to cover production costs. The U.S. countervailing duty case against potash exports, if not caused, at least coincided with both a reduction in Canadian output and a price increase.⁴ It is perhaps ironic that the Canadian Potash industry was the subject of an antidumping lawsuit. Saskatchewan producers, although they are of a different nature than those that made up the industry in the 1980s, had witnessed a U.S. dumping charge previously. In the 1960s, because of expanding capacity in Canada and the USSR, potash prices fell approximately 50% from 1965 to 1969. In the late 1960s, the economic hardship encountered by the higher-cost New Mexico producers caused layoffs of workers. As a result, political pressure developed to decrease the amount of potash

entering the United States. During the 1960s, Saskatchewan accounted for 93% of U.S. imports, which was 70% of Saskatchewan's production. The U.S. Treasury initiated charges of dumping against Canada. In August of 1969, the U.S. treasury deemed that dumping had occurred and referred the case to the U.S. Tariff Commission to determine the restrictions to be placed on potash entering the U.S. market. At the same time, the Saskatchewan government developed a prorationing scheme to increase the price of potash sold in the United States. Each Saskatchewan producer was granted a quota based on its proportion of total industry capacity. Also, a minimum price was established which, if violated, would lead to the cancellation of the operators' production license. The price set by Saskatchewan firms became the world price, and New Mexico producers were able to operate close to capacity.

The prorationing of the 1970s has made Saskatchewan firms aware of the benefits of co-operating. It caused the price of potash to increase by \$30 per tonne (constant 1980 \$Canadian) from 1969 to 1970. The total quantity produced in Saskatchewan decreased, but their profits increased because of the inelastic nature of potash demand. In 1973 there was a strong increase in demand for potash, and the program was abandoned in 1974 (Anderson, pp. 5-8).

Empirical Analysis

In calculating the rents lost and gained by the various groups from the U.S. antidumping case in 1987, the prices used were free on board (FOB) the potash mine. The prices were deflated to the 1982 level; therefore, all prices and welfare measures are given in 1982 dollars.

Olewiler (pp. 8, 9) estimated a series of average cost curves for various Saskatchewan mines and found that they were U-shaped with a relatively large region of constant unit cost. The cost included all mine and mill operating costs excluding taxation and depreciation. If the mines and mills were operated at full capacity (500,000 to 800,000 metric tons per year), then the average costs would be between \$30 and \$48 per metric ton of potassium oxide, or \$49 to \$79 per metric ton of potassium chloride (in 1982 dollars). In this analysis, the marginal cost used for Canada was based on an average of Olewiler's estimates, and the U.S. marginal cost was assumed to be 57% greater than Canada's mar-

⁴ A shortcoming of our analysis is that one cannot conclude that the price of potash increased as a result of the lawsuit. Perhaps PCS and others would have raised prices anyway. In conjunction with the countervailing duty case, the dynamics of firm behavior in cutting back output takes on many dimensions. PCS appeared to be the leader in raising prices and cutting output; other firms followed. However, for a time at least, PCS lost market share to some of its Canadian competitors. The pricing strategy followed by Canadian potash firms over time is a topic of further research and is not dealt with in this paper.

ginal cost. The estimates of the marginal cost, excluding transportation and retail costs, were \$40 for Canada and \$62 per metric ton of potassium oxide for the United States.

The transportation costs incurred by Saskatchewan and U.S. producers are approximately the same because most U.S. producers are located in New Mexico and, therefore, Saskatchewan and U.S. producers have similar distances to the major domestic market area in the Corn Belt region of the United States (the mid-western United States). The transportation costs will shift back and forth in favor of the Saskatchewan or U.S. producers, depending on the current transportation and economic policies as well as the market conditions. Generally, the northern states obtain most of the potash they consume from Canada, while the southern states are supplied by the Carlsbad, New Mexico, producers. The Saskatchewan and New Mexico producers compete mainly in the central states (Bennett, p. 43). In this paper, the transportation costs for the United States and Canada were assumed to be the same. Transportation costs from Saskatchewan to the major U.S. markets vary between \$42 and \$62 per metric ton of potassium chloride (1983–84 dollars), depending on the type of transportation. An average of \$31 per metric ton of potassium oxide was used for both Canada and the United States because they incur similar transportation costs. Transportation costs account for 25%–50% of the U.S. farmers' average retail price of potash. Fixed transportation and retail costs were included to determine the price paid by farmers.

The demand curve for fertilizer is generally considered price inelastic because there are few substitutes. The demand for potash is derived from the demand for the crops for which potash is an input (Fulton and Schmitz, p. 3). Bennett estimated the price elasticity in the U.S. market to be -0.38 from 1960 to 1980. Heady and Yeh found a price elasticity of demand in the United States to be -0.403 for the time period from 1926 to 1956. Hee estimated an elasticity of -0.46 from 1956 to 1965. Marhatta estimated a price elasticity of demand for aggregate U.S. potash for the period, 1950 to 1974, to be -0.53 . Olewiler (p. 12) estimated a long-run price elasticity of demand in North America from 1973 to 1984 to be -0.36 . Thus, an elasticity of -0.4 was used in the model.

In deriving the demand equations to calculate the user rents, the demand intercept was assumed to be changing while the slope remained constant. Therefore, the assumption was that the

demand was shifting from one time period to the next as a result of possible changes in the prices of corn and other grains that would affect the demand for potash. Allowing the intercept to shift is a more realistic approach than allowing the slope to change which would imply that the farmer response to a change in the price of potash was changing over time. This is illustrated in figure 3. If the demand curve for potash fertilizer shifts from D_1 to D_2 with a corresponding price increase from P_1 to P_2 , then user surplus has increased ($a_2c_2P_2 - a_1b_1P_1$) even though the price has increased. To quantify the impact of the countervailing duty action by the United States, the change in user surplus has to be estimated for a given demand curve. For example, if demand is D_2 and the price is increased from P_1 to P_2 due to legal action, then the change in user surplus is $P_2c_2b_2P_1$. From figure 3, in order to estimate the effects of the countervailing duty case, one has to compare periods before and after the litigation where demands are comparable.

The capacity of the U.S. potash producers was estimated using Korol's producer capacity utilization rates. The maximum value of the U.S. capacity estimated was 834,000 metric tons per six-month period based on a capacity utilization of 93% of production in 1979. The capacity level was assumed to remain constant over the data range from 1982 to 1988.

The rents are calculated for periods before and after the imposition of the tariff; the tariff level is based on the margin percentages imposed on the Saskatchewan firms when the duties were in place.

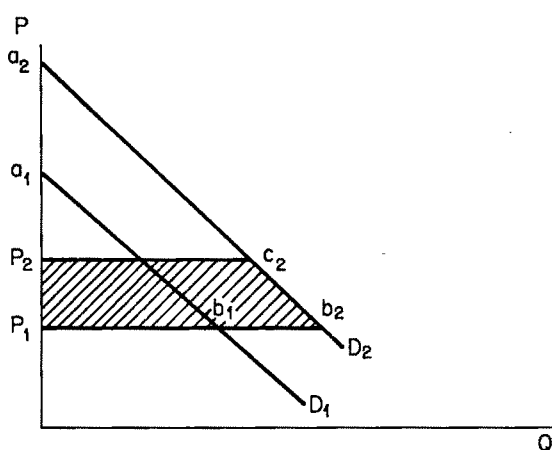

Figure 3. Measure of change in user surplus given a change in demand

The margin percentages for firms in Saskatchewan were:

Firm	Margin (%)
Potash Corporation of Saskatchewan	51.90
International Mineral and Chemical Corporation	9.14
Kalium Chemicals	29.67
Noranda, Inc.	85.20
Potash Company of America	77.40
All others	36.62

A weighted average margin, 41.43%, was used.

The estimated user and producer rents from 1982 to 1988 are given in table 1. In 1982, there was a large decrease in producer rents as prices and sales of potash declined sharply. Producer rents in the United States became negative in 1985 and remained so until 1988. Canadian rents became negative in 1986 and remained so until 1988. The Canadian marginal cost is lower than the U.S. marginal cost and, therefore, Canada did not incur a loss in surplus until 1986 (2).⁵ The large Canadian loss in 1987 (2) from sales in the United States was caused, in part, by the

tariff duties raising the Canadian marginal cost by 15% from 21 August 1987 to 8 January 1988.

The numbers show that after the imposition of the duties, U.S. producer rents were at least \$15 million higher in 1988 (2) than in 1986 (2).⁶ The corresponding number from the period 1986 (1) to 1988 (1) was roughly \$13 million.

As a result of the price increase and the elimination of the tariff duties, Canadian potash producer rents in 1988 (2) were roughly \$175 million higher than in 1987 (1). The gains from increased sales to the United States market exceeded the gains from offshore sales.⁷

The user rents fluctuate from year to year due

⁶ As the theory suggests, for Canada to maintain prices to avoid further countervailing duty action by the United States, Canadian firms have to adjust by cutting back production. As a result, in the North American market, U.S. producers' share would increase. This appears to be what has happened, and our estimates take market share changes into account. For the marketing year ending 30 June 1990, U.S. producers provided roughly one million metric tons to the U.S. market, which is greater than 20% of the market supplied by all North American producers. Prior to the imposition of the countervailing duties, this market share was generally 15% or less.

⁷ Offshore prices also rose and are positively correlated with U.S. prices. Because Canpotex's offshore prices follow U.S. prices with a lag, the offshore rent of \$55.4 million for 1987 is overstated (table 1).

⁵ Throughout the text, (1) refers to the period January–June and (2) refers to the period July–December.

to shifting demands brought about by, for example, changes in net farm income. As a result, the absolute user rents could increase from one year to the next even if prices increased. This is evident from table 1, where the absolute user rents are given for selected time periods.

The effect of potash duties on U.S. farmers can be seen by comparing the user rents between 1986 (1) and 1988 (1). Agricultural sales of muriate of potash were 2.499 million metric tons of potassium oxide, which was very close to the agricultural sales of 2.314 million metric tons in 1988 (1). User rents decreased by roughly \$73 million between 1986 (1) and 1988 (1).

In summary, the effects from the U.S. anti-dumping litigation against Canada during the period 1986 (1) to 1988 (1) were:

(1) U.S. Potash Producers	+\$ 12.9 million
(2) Canadian Potash Producers	+\$108.4 million
(3) U.S. Farmers	-\$ 70.4 million
Net Effect	+\$ 50.9 million

From the above, the Canadian firms were the

largest gainers from resolving the potash dispute between the United States and Canada. The losers were U.S. farmers. There was a net gain of roughly \$51 million. This is a conservative estimate since, by comparing other time periods, the Canadian potash producers gained much more than the \$108.4 million shown above. The above numbers show that, in aggregate, the "gainers" gained more from the lawsuit than the "losers" lost. From a U.S. perspective, however, it would have been in the best interest of U.S. farmers to bribe the U.S. potash firms to the tune of roughly \$15 million in order for them not to instigate legal procedures. It follows that, from a U.S. perspective, the "gainers" gained much less than the "losers" lost.

Pricing Strategy of Canadian Firms

In this section, we present results for selected time periods to determine the type of pricing behavior carried out by Canadian firms (table 2).

Table 2. Potash: Effects of Different Price Strategies (selected years)

Time Period and Price Strategy ^a	U.S. User Surplus	Producer Surplus	
		Canada	U.S.
		----- (U.S. \$ thou.) -----	
Prior to duty ^c

Note: Price strategy effects are based on the prices and quantities generated for the competitive, actual, and dominant strategies; elasticity of demand = -0.4

^a (1) refers to the period January-June; and (2) refers to the period July-December.

^b Under the competitive situation, the Saskatchewan firms have zero producer surplus since they set a price equal to marginal cost. The U.S. producers incur a loss if they continue to produce since their marginal cost is greater than the marginal cost of Saskatchewan producers.

^c Time period before duty was put in place

^d Time period while duty was put in place.

^e Time period after duty was suspended.

The rents generated by the actual strategy are compared with the outcomes from two alternative models: (a) Canadian potash producers act competitively; (b) they act as a dominant firm. The theoretical base was developed earlier. The results show that the actual behavior of potash firms is neither competitive nor dominant. The actual behavior seems to deviate significantly from either a competitive or dominant strategy. In comparing the dominant strategy with either the competitive or actual strategies, the rent effect for U.S. producers is much greater than for Canadian producers. That is, a dominant firm strategy increases the rents to U.S. firms to a greater extent than for Canadian producers. The theoretical model supports this conclusion because one is assuming that U.S. firms under a dominant pricing strategy continue to operate at capacity. However, in interpreting these results, the demand elasticity for potash plays a key role. The estimates in the table are based on an inelastic demand schedule for potash. However, the rents would be much lower from a dominant pricing strategy if the price elasticity for potash demand were elastic.

From a U.S. producer perspective, clearly, the dominant firm strategy generates the worst possible outcome. For example, under a competitive strategy, the user rents are at least three times greater than under a dominant firm strategy.

Conclusion

The two U.S. potash firms gained sizable rents from their rent-seeking strategy of lobbying their government to bring countervailing duty action against Canada. But the Canadian producers also gained as the U.S. removed the duties in response to Canada raising its export price. The U.S. antidumping action resulted in a cooperative solution where both the U.S. and Canadian producers gained rents at the expense of the U.S. users.

Our results show that the North American potash producers gained more from the U.S. antidumping action against Canada than what U.S. farmers lost. However, from a U.S. perspective, potash producers gained less than what farmers lost. Usually, in agricultural border disputes, the opposite is the case, in that they involve farm producers who gain by bringing antidumping charges against exporters.

Fortunately for U.S. farmers, even with the

threat of tariffs reappearing—in the event that future dumping might occur—Canadian potash producers are not using a dominant firm pricing strategy in the North American market. If the theoretical dominant firm strategy were followed, the U.S. producers would incur significant additional costs.

Effects of Technological Change and Institutional Reform on Production Growth in Chinese Agriculture

Shenggen Fan

Recent rapid agricultural production growth in Chinese agriculture could be attributed to an increase in inputs, technological change, and institutional reform. An accounting approach was used to separate the relative contribution of these three factors.

Institutional change, like the introduction of the household production responsibility system, has contributed to past growth in production. However, technological change is crucial to furthering production growth because of the limited potential for significant increase in the use of conventional inputs, in particular land. Continued institutional change must accompany corresponding technological changes.

Key words: agricultural production growth, China, frontier production function, institutional change, regional growth, technological change, total factor productivity.

From 1949 to 1986 agricultural production grew 4% a year in China (Fan). This growth was the most rapid among all the socialist countries (Wong) and even more rapid than growth in most developing countries (Hayami and Ruttan). Contributing to the rapid production growth was a series of technological and institutional changes and rapid increase of modern inputs. Since 1979, efforts have been made to improve incentives and stimulate production by decentralizing authority and responsibility for production decision to family units. Substantial improvement in productive efficiency has resulted.

Using a traditional accounting approach initiated by Solow, Perkins and Yusuf, and Wiens measured the total factor productivity in Chinese agriculture; however, the sources of productivity growth in their studies were not identified. Recently, some studies have measured the effects of institutional change on production and productivity growth. Lin (1987) attributed the

rapid growth in agricultural production from 1980 to 1984 to the household production responsibility system. He found that 20% of productivity growth, or 60% of agricultural production growth, was attributed to the institutional change. However, he ignored the effects of technological change on production and productivity growth. McMillan, Whalley, and Zhu used the accounting approach to capture the effects of reforms in prices and incentive systems on total productivity growth. Their results suggest that 22% of the increase in productivity in China's agriculture between 1978 and 1984 resulted from higher prices and 78% from change in the incentive system. They also ignored the effects of technological change.

The purposes of this study are to develop a new approach to capture the relative contributions of input growth, technological change, and organizational reforms to growth of agricultural production and to apply the approach to the major agricultural production regions of China. During the 1950s, the Chinese government divided the country into six administrative regions. This division is inappropriate for an analysis of agricultural productivity. However, formulating regions on differences in land use is not feasible because of data limitations. Therefore, in this study the country is divided into seven regions that take into account the availability of the agricultural data, the geographical features, and the current social and

cultural conditions. These regions adhere closely to the administrative division and are as follows: (a) Northeast (NE): Heilongjiang, Liaoning, and Jilin provinces. (b) North (N): municipalities of Beijing and Tianjin; Hebei, Henan, Shandong, Shanxi, Shaanxi, and Gansu provinces. (c) Northwest (NW): autonomous regions of Nei Monggol, Ningxia, Xinjiang, and Tibet; Qinghai province. (d) Central (C): Jiangxi, Hunan, and Hubei provinces. (e) Southeast (SE): Shanghai municipality; Jiangsu, Zhejiang, and Anhui provinces. (f) Southwest (SW): Sichuan, Guizhou, and Yunnan provinces. (g) South (S): Guangxi autonomous region; Fujian and Guangdong provinces.¹

Effects of Input Growth, Technological Change, and Efficiency Improvement

In traditional productivity theory, total production growth consists of movements along the production function (an increase of total inputs) and shifts of the production function (technological change), assuming that the firm is perfectly efficient in production. The growth rate of total factor productivity is the growth rate of total output minus the growth rate of total input; hence, technological change is considered the unique source of productivity growth, and the effects of efficiency improvement on productivity growth are ignored. The assumption of perfect efficiency in production is unrealistic. Differences among firms between realized output and potential output are caused by differences in the capacity to use new technological knowledge and in the motivations of farmers. If this assumption is relaxed, total production growth can be attributed to efficiency improvement as well as to increased inputs and technological change. Different policy inferences may be drawn inasmuch as technological change and efficiency improvement represent fundamentally different sources of growth in production. Therefore, a new approach will be developed to capture all three effects on production growth.

In this study technological change is defined as a shift of the frontier production function. Efficiency improvement is defined as the decrease in the distance between the firm's realized output and its potential output (or frontier). The different sources of production growth are shown in figure 1. At times 1 and 2, the producer faces

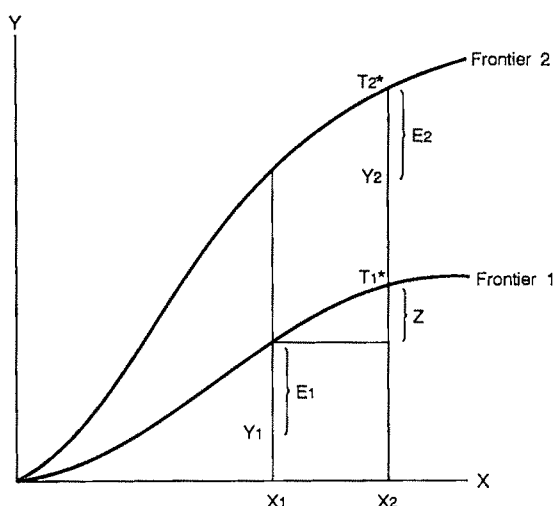

Figure 1. Effects on production growth of input increase, technological change, and efficiency improvement

production frontiers 1 and 2, respectively. If production were perfectly efficient, output would be T_1^* at time 1 and T_2^* at time 2. However, the producer's realized output is Y_1 at time 1 and Y_2 at time 2 owing to production inefficiency. Technological change is measured by the distance between frontier 2 and frontier 1, i.e., $T_2^* - T_1^*$. Inefficiency is measured as the distance between the frontier and the output realized by the producer, i.e., E_1 at time 1 and E_2 at time 2. Hence, the improvement of efficiency over time is the difference between E_1 and E_2 . The contribution of input change is measured as Z . Therefore, the total production growth can be decomposed to three effects: input growth, technological change, and efficiency improvement.

$$Y_2 - Y_1 = Z + (T_2^* - T_1^*) + (E_1 - E_2).$$

Prior to the introduction of the household production responsibility system to Chinese agriculture, production was organized by production teams or state farms. A farmer's income was not closely related to his production effort. After the reform, when producers became responsible for their plots, they worked harder, allocated resources more efficiently, and produced more output with the same input and technology. If only technological change is considered as the source of production and productivity growth, the effects of technological change will be overestimated by ignoring institutional change. Therefore, efficiency improvement is used in this study to capture the effect of insti-

¹ Hainan was not separated from Guangdong province.

tutional change on production and productivity growth.

Frontier Production Function

The frontier production function approach, initiated by Farrell in 1957, has been expanded by various methods of measuring and computing production functions and efficiency (Lovell and Schmidt). The main approaches include pure programming, modified programming, the deterministic statistical frontier, and the stochastic frontier. Pitt and Lee indicated that the programming approach and the deterministic frontier approach do not allow for random shocks in the production process; as a result, a few extreme observations can determine the frontier and exaggerate the maximum possible output. In this study, the stochastic frontier approach is employed to avoid this problem.

Consider the following production function:

$$(1) \quad Y_{it} = f(x_{it}, b)e^{v_{it}}e^{u_{it}}, \text{ or} \\ \ln Y_{it} = \ln f(x_{it}, b) + v_{it} + u_{it}$$

where i denotes the i th firm or region, and t denotes time t ; Y_{it} is output; x_{it} is $1 \times k$ rows of inputs; $f(x_{it}, b)$ is potential output; v_{it} is a stochastic variable representing uncontrolled random shocks in production; and u_{it} is one-sided distribution, $u \leq 0$, which represents technical inefficiency. In (1), $f(x_{it}, b)e^{v_{it}}$ is the stochastic frontier, given that v_{it} consists of random factors outside the firm's control. The nonpositive disturbance u indicates that output must lie on or below the frontier $f(x_{it}, b)e^{v_{it}}$ because $e^{u_{it}}$ has a value between zero and one. It is assumed that for $t \neq t'$, $E(u_{it}u_{it}') = 0$ for all i , and $E(u_{it}u_{it}') = 0$ for all $i \neq j$. In this specification, the firm's inefficiency may change over time by learning from experience. We also assume u is truncated normal with variance σ_u^2 , v is normal with mean zero and variance σ_v^2 , and $E(u_{it}v_{it}') = 0$.

The efficiency for a firm or region i at time t , then, is defined as

$$\frac{Y_{it}}{f(x_{it}, b)e^{v_{it}}}$$

Based on the conditional distribution of u_{it} , given the distribution $v_{it} + u_{it}$, the efficiency of a specific firm or region at a given time can be measured as (Kalirajan and Flinn)

$$(2) \quad E\left\{\exp\left(\frac{u_{it}}{u_{it} + v_{it}}\right)\right\} \\ = \exp\left[-\left(\frac{\sigma_u \sigma_v}{\sigma}\right)\left(\frac{f(\cdot)}{1 - F(\cdot)} - \frac{\varepsilon_{it}}{\sigma} \frac{\sqrt{\lambda}}{1 - \lambda}\right)\right],$$

where $\varepsilon_{it} = v_{it} + u_{it}$, σ is standard error of ε_{it} , $\lambda = \sigma_u^2/\sigma^2$, and $f(\cdot)$ and $F(\cdot)$ are the values of the standard normal density function and standard normal distribution function evaluated at

$$\frac{\varepsilon_{it}\sqrt{\lambda}}{\sigma(1 - \lambda)}.$$

The next step of the specification is to choose an appropriate functional form. Consider a production process that uses n inputs to produce one output represented by the production function

$$(3) \quad Y = f(x_1, \dots, x_n, T),$$

where Y is output, x_i is i th input and T is used to catch technical progress (time trend). The unrestricted translog form can be used to represent production function (3). However, the translog form needs considerable data and has many variables which may lead to multicollinearity problems. Consider a restriction that all inputs are separable from each other, but each input cannot be separated from technical progress:

$$(4) \quad Y = f\{g_1(x_1, T), \dots, g_n(x_n, T)\}.$$

The theoretical background of this form comes from the fact that every input changes over time while the effects among inputs are indirect through time. Then, the following production function form can be used to represent (4):

$$(5) \quad \ln(Y) = a_0 + a_t t + \sum_i a_i \ln(x_i) \\ + \sum_i a_{it} \ln(x_i) \times t + a_{it} t^2.$$

If all inputs and time are considered separable, the production function can be expressed as

$$(6) \quad Y = f\{g_1(x_1), \dots, g_n(x_n), T\}.$$

The Cobb-Douglas production function can be used to represent (6)

$$(7) \quad \ln(Y) = a_0 + \sum_i a_i \ln(x_i) + a_t t.$$

Owing to the serious multicollinearity prob-

lem of the translog form and the constancies of production elasticities in the Cobb-Douglas form, functional form (5) is used for the estimations. The Cobb-Douglas form and average production functions are also estimated for comparison purposes.²

Estimation of Production Functions and Efficiency

Panel data from twenty-nine provinces, municipalities, and autonomous regions in 1965, 1970, 1975, 1976, through 1986 are used in the estimations. Gross agricultural production value serves as the aggregate total output using 1980 constant prices. The subaggregates are (a) crop production, (b) forestry, (c) animal husbandry, (d) sideline industries, and (e) fisheries. Rural industry at all levels (including town, village, and teams) is excluded from agricultural production.³

Labor input in agriculture is measured by the numbers of employed persons at year end.⁴ The sum of sown areas and pasture is used to measure land input because the arable land data are inaccurate. Pasture areas are calculated in sown land area equivalence for output value, i.e., one unit of pasture equals .0124 of a unit of sown land (in 1985).⁵ Chemical fertilizer input is measured by pure nutrients, using the following percentage: 20% for ammonium sulfate, 18.7% for super phosphate, and 40% for potassium sul-

fate.⁶ Machinery input is measured by total horsepower at year end.⁷

Manurial fertilizer, which always has been very important in China, includes animal, human, and crop wastes; green manures; and water plants. In this study, manurial fertilizer is measured from the agricultural population (i.e., human waste) and numbers of domestic animals.⁸ Draft animals are measured at year end in units of heads that are used for agricultural activities and rural transportation. They include water buffaloes, cattle, horses, asses, mules, and camels.⁹ Irrigation input is measured as irrigated areas.¹⁰

The results of production function estimation for the different specifications are shown in table 1. The ordinary least squares technique is used for the average production function estimation and the maximum likelihood technique for the frontier production function. The Cobb-Douglas form is used for regressions 1 and 2. Time trend (T) measures neutral technological change over time. Except for machinery and irrigation, the coefficients of regressions 1 and 2 are very significant considering the crudeness of the data. However, the negative coefficients of draft animals are unrealistic. The sum of production elasticities of traditional inputs (except for draft animals) is more than .75, which implies that traditional inputs still dominate China's agricultural production. Chemical fertilizer input plays an important role in production. The significant and positive time trend coefficient

² The traditional estimation of a production function assumes that every firm is technically efficient, resulting in the average production function, i.e., $Y_{it} = f(x_{it}, b)e^{u_{it}}$, where u_{it} has normal distribution, $N(0, \sigma^2)$.

³ The time series of provincial monetary value of total production (measured in 1980 constant prices) before 1985 is reported in *Collection of Statistical Materials in National Income, 1945-1985*, State Statistical Bureau. The data after 1985 are reported in *China's Statistical Yearbooks*, 1986, 1987, State Statistical Bureau.

⁴ The provincial data of labor before 1980 are calculated from the provincial agricultural population.

$$L_{it} = P_{it} \times \frac{r_{i,80}}{r_{n,80}} \times r_{n,t},$$

where L_{it} denotes i th region's labor input in year t ; P_{it} , i th region's population in year t ; $r_{i,80}$, i th region's ratio of labor to population in year of 1980; $r_{n,80}$, national ratio of labor to population in year 1980. $r_{n,t}$, national ratio of labor to population in year t . The data for agricultural population before 1980 are taken from *National Agricultural Statistical Materials for 30 Years (1949-1979)*, State Statistical Bureau. The data of agricultural labor after 1980 are taken from various issues of China's statistical yearbooks.

⁵ The data for sown areas and pasture are taken from *National Agricultural Statistical Materials for 30 Years (1949-1979)*, State Statistical Bureau.

⁶ The data before 1980 are reported in *National Agricultural Statistical Materials for 30 years (1949-1979)*. The data after 1980 are taken from various issues of China's statistical yearbooks.

⁷ The horsepower of 1965 and 1970 is interpolated based on the numbers of hand tractors and other tractors. The horsepower from 1970 to 1975 is taken from the *National Agricultural Statistical Materials for 30 Years (1949-1979)*. The horsepower after 1980 is taken from various issues of the statistical yearbooks.

⁸ The FAO estimated that one animal (horse unit) produces about 4 tons of manure per year and a person produces .25 ton per year. Manure contains 2.2% pure nutrient, and the manure availability is about 75% of total use. Therefore, manurial resources are estimated as follows:

$$\begin{aligned} \text{Annual manurial resources (tons)} \\ = ((.25 \times \text{rural population} + 4 \\ \times \text{numbers of livestock}) \times 2.2\%) \times 75\%. \end{aligned}$$

The results of this estimation are not significantly different from that of Stone (Tang and Stone).

⁹ The numbers of draft animals before 1980 are taken from the *National Agricultural Statistical Materials for 30 Years (1949-1979)*. The numbers after 1980 are taken from various issues of statistical yearbooks after 1980.

¹⁰ The data of irrigated areas before 1980 are reported in *National Agricultural Statistical Materials for 30 Years (1949-1979)*. Those after 1980 are published in the various issues of statistical yearbooks.

strongly suggests that total factor productivity in Chinese agriculture has increased through neutral technological change.

Functional form (5) is used for regressions 3, 4, 5, and 6. Production elasticity for input i in this production functional form is $\partial \ln Y / \partial \ln x_i = x_i + a_{it}$. Thus, if $a_{it} > 0$, production elasticity of input i is increasing; if $a_{it} < 0$, production elasticity of input i is decreasing.

Regressions 3 and 4 use the same input variables as regressions 1 and 2. In addition, the

cross-term of each input and time trend captures the relative changes of each input in total input over time. The greater significance of the coefficients in regression 4 relative to those in regression 3 implies that the frontier production function used for estimation improved the results. Labor, land, draft animals, and manurial fertilizer play a decreasing role in production, whereas production elasticities of chemical fertilizer and machinery increase over time.

Because the coefficients of draft animals are

negative and the irrigation coefficients are not significant in regressions 1 through 4, these two variables are omitted in regressions 5 and 6. Some effects of draft animals on production are reflected by manurial fertilizer. The improvement in irrigation in China mainly occurs through increased irrigation power rather than an expansion in the size of irrigated areas. Therefore, these omissions do not greatly affect the estimation. Furthermore, these omissions avoid the collinearity among draft animals, manurial fertilizer, and land input. Most of the estimators in regressions 5 and 6 are significant. The omissions of draft animals and irrigation did not cause changes in other coefficients. Again, the frontier estimation is superior to the average estimation.

Table 2 shows that production elasticities (calculated using regression 6) of traditional inputs—land, labor, and manurial fertilizer—are decreasing: labor by 3.6% per year; land, 4.6%; and manurial fertilizer, 3.1%. The annual rates of increase of production elasticities for modern inputs—machinery, 6.5%; chemical fertilizer, 3.9%—are greater than the rates of decrease for traditional inputs.

The results in table 2 can be compared to those of other studies. For example, Ma, Calkins, and Johnson estimated the production elasticities (using 1984 data) for Shuyang county, Jiangsu province. The ranges in value for their elasticities were as follows: labor, .25 to .36; land, .17 to .20; chemical fertilizer, .17 to .23; manurial fertilizer, .08 to .11; and other inputs, .22 to .29. The elasticities vary depending on crops. Wong's estimation of the production functions (using 1960–80 data) for nine socialist countries resulted in the following production elasticities:

labor, .223; land, .143; chemical fertilizer, .177; machinery, .122; and livestock, .233. Comparing those to the production elasticities in table 2, we observe that the elasticities of land and labor in China are greater than those in the socialist countries, indicating that Chinese agriculture uses more traditional inputs than other socialist countries.

The level and variability of technical efficiency for each region are calculated in table 3, using (2) and the results of the frontier production function from regression 6. During the 1960s and 1970s, technical efficiency was about 70%. Efficiency has improved significantly since the institutional change in 1979. The institutional change has three effects: (a) Farmers' incomes and efforts have been linked through improved incentive systems. (b) Farmers may leave agriculture to engage in nonagricultural activities (mainly rural industry), thus improving the land/labor ratio. (c) Farmers may allocate their time and resources to produce high-profit crops, which has improved allocative efficiency and the full use of regional comparative advantages.

It is widely accepted that the introduction of the household production responsibility system enlarged the differences in income among regions (Jiang and Luo). However, there is no evidence that the differences in productive efficiency have increased—the coefficient of variation in productive efficiency has decreased since the reform (see the last column of table 3). The disparity between the production efficiency improvement and income growth among regions suggests that the substantial improvement in production efficiency in poor regions owing to the recent institutional reform did not result in a corresponding increase in income. One reason for this lack of response is the distorted prices in agriculture. Despite the substantial increase in prices in the last ten years, the agricultural product prices still are not reflected by supply and demand. Further reform in prices is needed to give farmers greater incentive to promote further production growth. Another reason is the uneven development of rural industry. The low level of income per capita, especially in the Southwest, is the result of the underdevelopment of rural industry.

Accounting for Total Production Growth

In this part an empirical approach is developed and used to separate the effects on production

growth of an increase in inputs, technological change, and institutional reform. Using functional form (5), the production function can be expressed as

(8)

$$\ln Y(t) = a_o + \sum_i a_i \ln x_i(t) + \sum_i a_{it} (\ln x_i(t)) \times t \\ + a_t t + a_{tt} t^2 + \ln(e^{u(t)}) + v(t)$$

$$(9) = \ln A_o(t) + \sum_i a_i(t) \ln x_i(t) + \ln E(t),$$

where $\ln A_o(t) = a_o + a_t t + a_{tt} t^2 + v(t)$, $a_i(t) = a_i + a_{it} t$, and $E(t) = e^{u(t)}$.

Taking the first derivative of (9) with respect to time t , the growth rate of total production can be accounted for as

$$(10) \quad \partial \ln Y(t) / \partial t = \partial \ln A_o(t) / \partial t + \sum_i a_i(t) \\ \times \partial \ln x_i(t) / \partial t + \sum_i \ln x_i(t) \\ \times \partial a_i(t) / \partial t + \partial \ln E(t) / \partial t.$$

The first term in (10) measures neutral tech-

nological change. The second term captures the effect of input change on production growth; it is the sum of growth rates in inputs weighted by the relevant production elasticities. The third term measures the effects of biased technological change on production growth; if it is positive, output has increased through biased technological change (using abundant resources to substitute for scarce resources). The last term reflects the effect of institutional change (or efficiency improvement) on production growth.

Using (10), the accounting for the sources of total production growth is presented in table 4. Neutral and biased technological change are considered as total technological change in the accounting and treated as the residual. For the whole country, total production growth rate was 5.04% per year from 1965 to 1985; 57.7% of the growth is explained by increased use of total input and 42.3% by growth in total factor productivity. About 63% of productivity change is attributed to institutional change (or efficiency improvement) and about 37%, to technological change. The increase of labor still explains about 7.7% of total production growth. The change of land input had the least effect because acreage

used for agriculture remained nearly constant. Among all inputs, increased chemical fertilizer input contributed most significantly to production growth (26.2%), while manurial fertilizer explained 5% of total production growth. The increase in machinery use is the second most important factor in total production increase.

The differences in sources of production growth among regions are substantial because of differences in the resource endowments and total factor productivity growth. Growth in total agricultural production varied from 3.70% in the Northwest to 5.88% in the North region. The contribution of total input growth to production growth varies from 50.9% in Southeast to 83.2% in Southwest. The differences in modern input (chemical fertilizer and machinery) growth explains most of the differences in total input growth. Among modern inputs, chemical fertilizer has the largest effects. The differences in traditional input growth are small.

The differences of the effects of institutional change on production growth explain the largest share of the differences in total production growth, ranging from 2.5% in Northeast to 44.4% in North. The contribution of technological

change to production growth also has varied substantially among regions. Total factor productivity growth in the Northeast is mainly explained by technological change. Technological change contributed more than 45% of the total factor productivity in the Southeast. However, technological change in the North, Northwest, and Southwest contributed little to total factor productivity and total production growth.

Concluding Comments

The major findings of this study are summarized as follows: The estimates of the frontier production functions indicate that traditional inputs are still important to China's agriculture. However, the importance of the traditional inputs of land, labor, and manurial fertilizer is decreasing rapidly. In contrast, the coefficients of modern inputs, e.g., chemical fertilizer and machinery inputs, were small in 1965 but have since increased rapidly. By 1985, the modern inputs were as important as the traditional inputs.

Efficiency measurements indicate that the household production responsibility system has

contributed significantly to production growth. However, the regional differences in performance are large. In general, land-scarce regions gained more from the reform.

The accounting for production growth showed that a significant share of total production growth still can be attributed to increases in traditional inputs. Among all inputs, increased chemical fertilizer use was the most important source of production growth. Increased machinery input ranked second in importance. Total input growth explained 57.7% of total production growth. The residual, the proxy for technological change and efficiency improvement, accounted for 42.3% of total production growth. Institutional change has had greater effects on productivity and production growth than has technological change.

These findings have important policy implications in promoting further production growth and smoothing regional inequalities. China's population reached 1065.29 million in 1987. The population growth rate from 1949 to 1987 was 1.84%, although it declined to 1.29% in last decade. Further decreases in population growth will not be easy in the next decade because the base population is large and those born in the 1960s are entering reproductive age. Thus, the demand for food will continue to grow even apart from income effects. The demand for cash crops is increasing with the development of industrialization. How to meet the future demand for rapid increases in food and in industrial materials is an urgent problem.

Increased Input Use

The quickest solution for China is to increase the use of inputs, such as land, labor, chemical fertilizer, machinery, and others. However, the total land input is likely to decline in the future (Sun). Without an increase in land areas, an increase in labor will have only a limited effect on total production. Increased use of modern inputs, especially chemical fertilizer, likely has the greatest potential for increasing total production. Although fertilizer input per unit of land in China is higher than in most developing countries, the output increase from greater fertilizer use is still potentially large in some regions (see table 4), particularly in the Northeast, Northwest, North, and Southwest. Increased machinery input will have little effect on production unless it increases land productivity. Thus, a top priority in mechanization involves increased land productivity (e.g., mechanization of irrigation).

Technological Change

The results of this study indicate that technological change accounts for 15.7% of total agricultural production growth in China. Compared to other countries, this proportion is very small. In Japan, from 1960 to 1980, 47.4% of total production growth stemmed from technological change, and technological change accounted for 84.2% of the growth in U.S. total output (Hayami and Ruttan).¹¹ Underinvestment in agriculture may explain the slow technological change in China. In 1985, the agricultural sector produced 28.1% of total national output and 41.1% of national income, although the agricultural investment was only 3.4% of total investment (*China's Statistical Yearbook*, 1986). The underinvestment in agriculture has resulted in poor rural infrastructure and insufficient agricultural research. An increase in agricultural investment, especially in research and development, is needed to stimulate technological change.

Institutional Change

Recent institutional changes have improved agricultural production efficiency greatly; 26.6% of production growth has been contributed by institutional change. The new strategy should focus on greater regional specialization, based on comparative advantages. The self-sufficiency policy both at the national level and local levels should be discarded. Crops should be grown where soil and climate provide the most favorable conditions. Although rural labor has more opportunities to work outside agriculture, labor immobility will become a major source of inefficiency. The pattern of land holdings (in terms of size distribution of farm), land tenure and other contractual arrangements in agriculture should be adjusted appropriately to gain more efficiency. The recent introduction of factor and product markets in agriculture has contributed to more efficient allocation of resources; however, instability of input and output prices and the insufficient supplies of modern inputs will continue constrain agricultural production.

¹¹ See table 7.2, Hayami and Ruttan (1985 ed.). Total output growth is 1.9% a year in Japan from 1960 to 1980; total productivity growth (the contribution of technical change to output growth), .9%. Thus, the relative contribution of technical change to total output growth is 47.4%. Using the same calculation, the relative contribution of technical change to total output growth is 84.2% in the United States.

Smoothing Regional Inequalities

Differential growth rates in agricultural development among regions of a country represent a persistent challenge to policy makers. Smoothing the differences in technological and institutional changes among regions is needed to reduce the differences in production and income growth. A well-integrated and extensive physical infrastructure and a strong regional agricultural research capacity adapted to the needs of the regional agricultural economy are important in contributing to development of new comparative advantages in technology in the regions disadvantaged by resource endowments and to stimulation of more even rates of technological change across regions.

New agricultural policies and institutional changes should create more geographically even growth in agricultural production and income. For example, crop prices should be raised in order to narrow the income differences between the regions with an advantage of crop production but with a disadvantage of rural industry, and the regions with well-developed rural industries.

Farmer Behavior Under Risk of Failure

William E. Foster and Gordon C. Rausser

We analyze input decisions under risk of farm failure. Inputs with immediate cash outlays have greater effective than observed prices because their cost increases the probability of failure, and their optimal marginal products are higher than observed prices would warrant under strict profit maximizing without failure risk. An algebraic example illustrates the market equilibrium effects of failure risk. We apply the model to an analysis of Illinois corn production (1971–79). Results indicate that larger farms deviate less than smaller farms from strict profit maximization. Over the period studied, farmers moved further from setting marginal products equal to observed prices.

Key words: corn production, farm failure, input decisions, risk.

This article addresses input decisions under risk of farm failure. Without risk of failure, the farmer would first maximize his expected utility as if he relied only on farm revenue (including concurrent off-farm employment, if applicable) and then compare this level of farm-derived utility with the utility available elsewhere (less moving expenses, etc.). If the farm-derived expected utility exceeds nonfarm utility, the farmer remains a farmer. With risk of failure, however, if the farmer chooses to continue another season, the ensuing revenues may be so low as to preclude future decisions to stay in agriculture (i.e., failure). The critical level of revenue below which the farm fails may be a function of household-maintenance expenditures, farm debt, and so forth. This level is likely to rise with farm size, but at a decreasing rate. Therefore, smaller scale, commercial farms are more likely to be at risk than larger farms.

The discrete difference between on-farm and off-farm returns leads to asset fixity (for example, see Johnson and Quance, Johnson and Pasour). A farmer's human capital fixity, in particular, presents important complications to conventional economic analysis of agricultural supply, which relies on strict maximization of expected utility (or of expected profit) derived solely from farm production. If the difference

between on-farm and off-farm utility is large, the farmer will take actions to avoid leaving agriculture; these actions may lead to seemingly inefficient farm management decisions. Robison, Barry, and Burghardt, for example, explore the use of credit as a means of forestalling costs associated with liquidating fixed assets to meet cash flow obligations. Their model implies that a farmer has a greater incentive to acquire debt as bankruptcy grows more likely, consistent with the "go-for-broke" behavior seen in highly stressed borrowers.

Also important is the influence of the risk of failure on farm input decisions. The purpose of this paper is to draw out the implications of failure risk on farm production decisions, specifically on the differing incentives to use cash-draining inputs in contrast to those inputs that do not require immediate cash outflow. The second section presents a model of input use where there is a difference between on-farm and off-farm returns to a farmer's human capital and shows that, under failure risk, the use of non-cash-draining inputs may increase with a decrease in output price. The third section presents a specific partial equilibrium model to illustrate the concepts developed in the second and to demonstrate the possible effects of failure risk on equilibrium output price. The fourth section turns to the practical application of the ideas developed in this study and to the role commodity programs play in reducing the effect of costly farm failure. The empirical analysis is of corn production in Illinois, using the model of how the threat of failure affects input choices. The

study focuses on the effects of farm size and other structural variables on farmer divergence from strict profit maximization.

Farmer Behavior Under Risk of Forced Adjustment

Two major sources have been hypothesized regarding the fixity of physical assets. The first involves the lumpy nature of the production process. Galbraith and Black, for example, hypothesize that large fixed costs associated with reorganizing the farm operation make short-run adjustment unprofitable. Changes in the economic environment would induce changes in productive capacity only if they were of sufficiently high magnitude and of sufficiently long duration. The second source of fixity involves the difference between the on-farm value of assets and their alternative, off-farm value (Johnson and Quance). Low salvage value may reflect transportation costs, specificity of capital to the farm operation, and limited, asymmetric information regarding quality of the item (Akerlof 1970, 1980). Whatever the cause of low salvage values, once acquired, productive capacity changes only with discrete (perhaps large) changes in the on-farm-use value.

A farmer's human capital is subject to a similar fixity. Although a farmer's labor may be divisible between on-farm and off-farm employment, his human capital specific to farm management is lumpy. Or from another perspective, one may view the "salvage" value of human capital (the opportunity cost of being a farm manager) as less than the on-farm value (the opportunity cost of not being a farm manager). The discrepancy between a farmer's salvage value and his on-farm value may reflect the specificity of the capital and/or the personal, or psychic, premium on earning an income from owning and operating a farm.¹ In dollars (accounting for moving costs, etc.), a farmer may seem to have a high salvage value, but in utility, derived from these nonfarm dollars, the salvage value is low.

A notable distinction between a farmer's human capital and other factors that may be sub-

ject to fixity is that certain minimal expenditures are necessary in order to stay in farming. The farm family must eat, clothe itself, and otherwise live happily alongside its neighbors. In addition, the decision to farm may incur other fixed commitments: minimal debt service, minimal use of certain publicly provided goods (e.g., water), insurance, and so forth.

The adjustment of a farmer's human capital out of agriculture is not always an active decision. Forced adjustment occurs when farm production does not cover the minimal, necessary costs. Without this risk of forced adjustment, or failure, the farmer would simply compare the expected utility of farming with the utility of leaving farming and make the optimal discrete decision to continue. Instead, the risk of failure leads to seemingly inefficient production decisions.

Input response to risk may entail anything from too quickly depleting soil quality, to placing greater stress on farm labor at the expense of leisure.² Inputs that are purchased prior to the production process are underutilized in the sense that their marginal products are higher than what would be optimal under strict maximization. Those that can be utilized without immediate cash expenditure ("mined" or "borrowed off"), such as soil quality and farm household labor, are overutilized. Commodity production may be increased or decreased, relative to the case where there is no difference between on-farm and off-farm utility, depending on the degree of complementarity of factors.

An Algebraic Model

A model of a farmer's behavior under risk of failure is inherently intertemporal. The farmer must trade off the amount of utility he gets in any year from farming with the probability of failure.³ Intertemporal models may lead to intractable complications; therefore, the following mathematical model makes certain simplifying assumptions. Specifically, the farm manager faces a discrete difference between on-farm and off-

¹ One reviewer points out the possibility that the farmer, having failed, may work for other farmers, thereby employing (at least some of) his farm-specific skills. These employed skills, however, would likely be strictly related to farm labor rather than management of inputs (including labor). Nevertheless, the opportunity cost of the farmer's management of a farm may be the value of employment by other farmers rather than employment out of agriculture altogether. Furthermore, the utility of this farm labor may be much less than that derived from farm management.

² For example, Thompson, Gwynn, and Sharp report the survey of married farm women in Yolo County, California, and remark: "The increased participation by women on smaller farms was found to result from the need for the entire family to use its total resource for survival rather than to a greater opportunity for women to participate on small farms."

³ The models presented in this and the following section are similar to those discussed by Just and Zilberman. The basic model offers an explanation of farmer behavior that resembles behavior arising from a safety-first objective function (Pyle and Turnovsky).

farm returns; random events are independent over time; the alternative utility that the farmer receives off the farm, if he fails, is a constant value; and, once failed, the farmer leaves farm management forever. These assumptions produce the following results. Farm decision rules as functions of prices are constant over time; the expected farm-derived utility in any period is constant; the cost of moving out of agriculture is the difference (also constant) between optimal yearly expected farm-derived utility and off-farm utility. Furthermore, the farmer's objective function can be written in terms of yearly expected farm-derived utility, off-farm utility, and the probability of failure.

A farmer yearly produces a commodity, the per-acre amount of which is denoted by y , by combining two factors of production: (a) x are those which must be yearly purchased out of cash revenues prior to realization of actual production and price received, and (b) k are those which may be utilized in the year but paid for in the indeterminate future. Examples of the factor x include hired labor, fertilizer, etc. Examples of input k include land quality, farm household labor, owned machinery, etc. The per-acre production function in a given year is given by

$$(1) \quad y = y(x, k, \varepsilon),$$

where ε represents some random effect on output y , such as weather. The number of acres produced is given by A , which is a constant. The farmer faces every year an unknown price p , a random variable ($p > 0$, $E[p] = \mu$), with some time-invariant probability density function given by $g(p)$. The constant per-unit cost of the factor x is given by w , and of factor k is given by i .

Failure is defined as inability to cover the minimal expenditures in a year necessary to farm, f ; that is, failure is defined by

$$(2) \quad A[py - wx] < f.$$

If the farmer fails, he leaves farming and earns some sure utility level I each year thereafter. For ease of presentation, we assume that production is certain and price is the only random variable. This particular assumption is relaxed in the next section.

The yearly probability of failure, π , is given by $\pi(x, k) = \int_0^{p_d} g(p) dp$, where $p_d y - wx = f/A$. The utility from farming in any year is given by

$$(3) \quad U(p, x, k) = U[A(py - wx - ik)],$$

and the expected utility from farming is simply

Table 1. Future Utility Levels Conditioned on Farm Failure

Discount Factor	Probability of Income Stream				
	π	$\pi(1 - \pi)$	$\pi(1 - \pi)^2$	$\pi(1 - \pi)^3$	
1	U_F	U_N	U_N	U_N	...
β	I	U_F	U_N	U_N	...
β^2	I	I	U_F	U_N	...
β^3	I	I	I	U_F	...
β^4	I	I	I	I	...
...
...

Note: $U_F = E[U | p < p_d]$, and $U_N = E[U | p \geq p_d]$.

$$(4) \quad \bar{U}(x, k) = E[U(p, x, k)].$$

Finally, the constant discount rate for future expected utility (either from farming or not farming) is given by β . Define \bar{U}_N as the expected value of utility from farm income conditional on not failing, \bar{U}_F as the expected value conditional on failure; that is, $\bar{U} = (1 - \pi)\bar{U}_N + \pi\bar{U}_F$.

Table 1 presents possible future events that the farmer must consider if he chooses farming. After summing over all possible streams of utilities,⁴ one may represent the farmer's objective as

$$(5) \quad \bar{V}(x, k) = \frac{\pi \frac{\beta}{1 - \beta} I + \bar{U}(x, k)}{1 - \beta[1 - \pi(x, k)]};$$

The term $I\beta/(1 - \beta)$ is the expected earnings from agricultural work, after failure. (Note the discount factor on this off-farm income is $\beta/(1 - \beta)$, not $1/(1 - \beta)$, because the farmer starts earning I the year following failure.) The term

⁴ Sum along the central diagonal of table 1, taking the product of the expected utility in any year, the probability of obtaining that expected utility, and the appropriate discount factor:

$$\begin{aligned} \bar{U}_F \pi + \bar{U}_F \pi(1 - \pi) + \dots &= \bar{U}_F \sum_{i=0}^{\infty} \beta^i (1 - \pi)^i \\ &= \bar{U}_F \pi / [1 - \beta(1 - \pi)]. \end{aligned}$$

Sum along a representative diagonal j steps to the left of and above the central diagonal:

$$\begin{aligned} \bar{U}_N \pi(1 - \pi)^j \sum_{i=0}^{\infty} \beta^i (1 - \pi)^i \\ &= \bar{U}_N \pi(1 - \pi)^j / [1 - \beta(1 - \pi)], \quad j = 1, 2, \dots \end{aligned}$$

Sum along a representative diagonal j steps to the right of and below the central diagonal:

$$I \beta^j \pi \sum_{i=0}^{\infty} \beta^i (1 - \pi)^i = I \beta^j \pi / [1 - \beta(1 - \pi)], \quad j = 1, 2, \dots$$

Sum all the diagonal summations to obtain expression (6).

$[1 - \beta(1 - \pi)]$ represents the discount rate of future incomes. As the probability of failure increases, the farmer would tend to discount the future more heavily.

A more compact representation of the farmers criterion function is derived by subtracting from \bar{V} in expression (6) the income stream if the farmer left agriculture before the first year:

$$(6) \quad V(x, k) = \bar{V}(x, k) - \frac{1}{1 - \beta} I \\ = \frac{\bar{U}(x, k) - I}{1 - \beta[1 - \pi(x, k)]}.$$

The value $V(\cdot)$ represents the rent, or surplus, from being a farm owner. The numerator, $\bar{U} - I$, represents the farmer's expected surplus in any given year. The value $I/(1 - \beta)$ is the salvage value of a farmer's human capital. When $V(x, k) > 0$, a farmer's human capital is fixed for limited changes in \bar{U} and I .

Let k^* and x^* satisfy the first-order conditions of maximizing the objective function given by expression (7):⁵

$$(7a) \quad \frac{\partial y}{\partial k} = \frac{iE[U']/E[U'p]}{1 + \theta}$$

$$(7b) \quad \frac{\partial y}{\partial x} = wE[U']/E[U'p] \frac{1 + \theta E[U'p]/E[U']p_d}{1 + \theta}$$

$$(7c) \quad \theta = V\beta g(p_d)p_d/[AyE(U'p)].$$

Here, marginal utility is given by U' . The parameter θ measures the influence of human capital fixity (measured by V) on farm production decisions. Expression (8c) makes explicit that the influence of human capital fixity on production depends on several elements: the discount rate, the probability distribution of price, farm size, and the correlation of marginal utility and price. If fixity has no influence on production decisions, then $\theta = 0$; and as θ grows, production decisions deviate from strict maximization.

Compare these first-order conditions to that of strict maximization of $E[U]$:

$$\frac{\partial y}{\partial k} = iE[U']/E[U'p]$$

$$\frac{\partial y}{\partial x} = wE[U']/E[U'p].$$

Because $\theta > 0$, the farmer appears to overutilize k based on conventional marginal conditions. Further, it is reasonable to suppose that the critical price defining failure, p_d , is small relative to expected price. If p_d is such that $E[U'p] > E[U']p_d$, then the farmer appears to underutilize x .⁶

Now suppose the rest of the economy improves relative to the agricultural sector. As the costs of failure ($\bar{U} - I$) grows insignificant, then $\theta \rightarrow 0$, and the farmer behaves as if he were maximizing the utility derived solely from farming (\bar{U}). We may interpret $g(p_d)$ as a measure of the degree to which a farmer can marginally influence the probability of failure via production decisions. For example, if random price were associated with a familiar bell-shaped probability density function, then farmer input decisions decreasing p_d by a unit at low levels would have less effect on the probability of failure than if p_d were decreased by a unit near the mean price. Suppose the probability distribution of commodity price changes such that $g(p_d) \rightarrow 0$ (that is, suppose the bell-shaped density of price shifts rightward with an increase the mean price), then farm decisions move toward production efficiency. Regardless of potential cost of failure (i.e., $\bar{U} - I$), if there is no influence at the margin, $g(p_d) = 0$, then again the farmer acts as if he were maximizing farm-derived utility. One point to be emphasized from this discussion of expression (8) is that in this model human cap-

⁵ Equations (8a), (8b), and (8c) derive from the following first-order conditions for the maximization of the objective function (7):

$$\frac{\partial V}{\partial k} = D^{-1} \frac{\partial y}{\partial k} A[E(U'p) - E(U')] + VD^{-1} g(p_d) \beta p_d \frac{\partial y}{\partial k} y^{-1} = 0, \\ \frac{\partial V}{\partial x} = D^{-1} \frac{\partial y}{\partial x} A[E(U'p) - E(U')] + VD^{-1} g(p_d) \beta p_d \frac{\partial y}{\partial x} y^{-1} \\ - VD^{-1} g(p_d) \beta w y^{-1} = 0,$$

where $D = 1 - \beta(1 - \pi)$.

⁶ The specification of survival—covering minimal expenses—is stylized in one important way. Minimal expenses, f , is a constant, and specifically not an increasing function of three items: farm size, input use, or past failure to cover all expenses (i.e., some portion of past ik). Although relaxing the current simplification would complicate the analysis, to make f a function of the first two items would not alter the basic implications of the model as long as f increases over these items at a decreasing rate. The third item is conceptually more important. If the farmer delays payment on some portion of the cost of inputs k , one expects that portion to contribute to higher minimal expenditures in the future (or perhaps decreased output) and thus a higher future probability of failure for all levels of inputs. This would tend to blur the distinction between x and k in the active avoidance of failure. Nevertheless, as long as the farmer does not have to pay a price of delaying payment that exceeds his discount rate, and at failure time all delayed payments outstanding are forgotten, then k would be a more attractive input than x using the simple criterion of minimizing the probability of failure.

ital fixity ($V > 0$) is necessary but not sufficient to cause "inefficient" production decisions.

With the general representations of $V(\cdot)$ and $g(\cdot)$, one cannot immediately determine the effect of changing farm size on the optimal choices of factors. Although p_d decreases with an increase in A , which decreases θ , $g(p_d)$ may decrease or increase. In addition, V increases with an increase in farm size, positively affecting θ . If, however, p_d is small relative to μ , then $g(p_d)$ likely decreases with farm size (as would be the case if p were normally distributed). The effect of decreasing f , and thus decreasing the probability of failure, would bring k^* and x^* into line with productive efficiency.

To be more specific, suppose the farmer is risk neutral; that is, $E(U')/E(U'p) = 1/\mu$. The first-order conditions may then be written as

$$(8a) \quad \frac{\partial y}{\partial k} = \frac{i}{\mu} / (1 + \theta)$$

$$(8b) \quad \frac{\partial y}{\partial x} = \frac{w}{\theta} \left(1 + \theta \frac{\mu}{p_d} \right) / (1 + \theta)$$

$$(8c) \quad \theta = V\beta g(p_d)p_d / (A\mu y).$$

As noted above, relative to $\theta = 0$, the marginal product of k is set lower and the marginal product of x is set higher. (This is true given $p_d < \mu$.) What happens to the actual levels of k and x depends on the degree of substitutability. For example, suppose k and x represent single factors. Let the parameter θ begin from a point where fixity has no influence on production, either because the cost of failure is zero ($V = 0$), or because the farmer has no influence at the margin over the probability of failure ($g(p_d) = 0$). The following comparative statics show the effect on factor decisions due to an increase in θ , indicating an increase in the influence of fixity. Differentiating (9a) and (9b) with respect to k , x , and θ yields:

$$\frac{\partial k}{\partial \theta} = \frac{-1}{\Delta} \left[y_{xx} \frac{i}{\mu} - y_{xk} \frac{w}{\mu} \left(1 - \frac{\mu}{p_d} \right) \right]$$

$$\frac{\partial x}{\partial \theta} = \frac{-1}{\Delta} \left[y_{kk} \frac{w}{\mu} \left(1 - \frac{\mu}{p_d} \right) - y_{xk} \frac{i}{\mu} \right],$$

where $\Delta > 0$ is the determinant of the matrix of second partial derivatives of y with respect to x and k , which is assumed negative definite. Not surprisingly these effects are of ambiguous sign. However, if the two inputs are substitutes (i.e., y_{xk}), then the effect of increasing the mea-

sure of fixity, V , or of increasing at the margin the farmer's influence on the probability of failure, $g(p_d)$, is to decrease the use of cash-draining inputs and increase the use of those inputs which are not cash draining: $\partial k / \partial \theta > 0$ and $\partial x / \partial \theta < 0$. This will hold for some x and k where the inputs are complements, that is, where y_{xk} is positive but sufficiently close to zero. The derivative of total product with respect to θ represents the effect on supply of increasing the importance of immediate cash revenues. Increasing the deviation of optimal input decisions from strict profit maximization may either increase or decrease supply, again depending on the degree of substitutability of inputs:

$$\frac{\partial y}{\partial \theta} = y_k \frac{\partial k}{\partial \theta} + y_x \frac{\partial x}{\partial \theta}.$$

Note that for $\theta = 0$, one can solve the above comparative static results to find that the sufficient condition for output to increase is given by $y_{xk} < w/i y_{kk}$.

The marginal conditions in (8a), (8b), and (8c) can be viewed more generally by writing the first-order conditions, given by expressions (8), as

$$(9a) \quad \frac{\partial y}{\partial x} = \rho_1 \frac{w}{\mu}$$

$$(9b) \quad \frac{\partial y}{\partial k} = \rho_2 \frac{i}{\mu},$$

where the ρ 's reflect a general systematic rule of behavior, with strict profit-maximization as a special case ($\rho_i = 1$). From expressions (9), the ρ 's are related through their mutual dependence on θ , μ , and p_d : $\rho_1 = \rho_2(1 + \theta\mu/p_d)$. These ρ 's are termed adjustment factors. For practical purposes, we take the ρ 's as functions of certain observable variables, which are not simultaneously also choice variables.⁷ For example, in the empirical section that follows, it is through government programs' influence on these adjustment factors that one determines the effectiveness of programs at reducing the effect of risk of farm failure.

A Special Case: An Overproduction Trap

This section considers a specific model of a producer's behavior under risk of forced adjust-

⁷ This approach is similar to that taken by Lau and Yotopoulos in their investigation of relative production efficiency. Lau and Yotopoulos take the ρ 's as constants over time for a given type of "farm." Their data uses averages of individual farms as a given size and region.

ment. This example is presented in two parts. In the first, the producer avoids risk by expending greater effort in producing a cash income in order to increase the likelihood of covering the minimal necessary expenditures to retain farm ownership. The purpose here is to show the possibility of a backward-bending supply curve, the discrete jumps in supply that may occur at various level of expected price, and the conditions under which a reduction in price variance reduces supply and improves productive efficiency.

The second part of this example considers market equilibrium. A stable, long-run equilibrium is defined where the probability of forced adjustment is zero and where expectations are rational. This example shows that rational-expectations equilibria can arise where the producer is permanently taking the risk of failure into account when making production decisions (i.e., producing "inefficiently"), but the observed probability of failure is zero.

We will term the producer behavior where output expands in response to falling output price survival mode and the equilibrium where supply is backward bending with a zero probability of failure, a survival mode equilibrium. If an outside observer finds a small probability of forced adjustment or failure, this does not necessarily imply the farmer is out of survival mode and making decisions based on maximizing farm-income-derived utility. Causality may flow the other way. This example demonstrates a case in which zero probability of failure exists, the farmer is rationally producing "inefficiently" (i.e., contrary to strict profit maximization), and supply increases with a fall in expected price. The important point is that the probability of failure is low (in this case, zero) because the farmer produces in this (strictly defined) inefficient manner.

Furthermore, if a survival-mode equilibrium exists with an inelastic demand curve, then another rational-expectations equilibrium with productive efficiency also exists. This two-equilibria condition illustrates an overproduction trap. That is, as a result of overproduction, market conditions are such that overproduction is optimal for individual farmers. Moreover, if in concert farmers reduced production to that of a conventional equilibrium, no individual would have incentive to expand. With an elastic demand curve, a survival-mode equilibrium may exist, but this cannot strictly be called a trap because only a single rational-expectations equilibrium exists.

Suppose there is one competitive farmer in the market producing some level of commodity, y , out of effort, e , and receiving some level of price, p . Production is random, and, therefore, so is price. Although price depends on quantity, the farmer acts as if he had no influence over its probability distribution function. Let the utility function from farming be the sum of the goods consumed out of farm revenues, py , over some minimal expenditure f , and leisure time: $U = (py - f) + (1 - e)$. This utility function implies a constant marginal utility of income and exhibits Arrow-Pratt risk neutrality. Random production is given by $y = 2e^{1/2}\varepsilon$, where ε is a random term taking on two values (associated say with bad and good weather), $\varepsilon = \varepsilon_l$ or $\varepsilon = \varepsilon_h$ ($\varepsilon_l < \varepsilon_h$), with equal probability. Let \bar{y} represent the expected or average yield, that is, $\bar{y} = 2e^{1/2}$. The demand curve is of constant elasticity $p = ay^{-b}$. Therefore, random revenues can be written as

$$(10) \quad py = a(2e^{1/2})^{-b} 2e^{1/2}\varepsilon^{1-b}$$

This problem with output and price random can be reduced to a simpler conceptual problem with only one source of randomness. It is conceptually easier to redefine price as having an expected value of $\mu = a\bar{y}^{-b}$ with multiplicative error of $u \varepsilon^{1-b}$, where without loss of generality $E[u] = 1$. Now the new random term u can take on two values associated with the two values of ε : $u = u_l$ or $u = u_h$ ($u_l < u_h$). The competitive farmer acts as if he cannot influence expected price; the farmer views revenues as $py = \mu u 2e^{1/2}$. The failure condition is where $py < f$, or where $e < (f/2\mu u)^2$.

To summarize, the farmer's objective function is given by

$$(11) \quad V = \frac{\bar{U}(e) - I}{1 - \beta(1 - \pi)},$$

where $\bar{U}(e)$ is the expected farm-derived utility, I the alternative utility of leaving farming, β the personal discount rate, and π the probability of failure. The probability of failure may take on three values depending on the chosen level of output. If the farmer expends so little effort that even at the highest possible price cash receipts do not cover minimal expenses, then the probability of failure is one. If, on the other hand, the farmer expends enough effort so that even at the lowest possible price receipts cover minimal expenses, then the probability of failure is zero. For levels of effort in a middle range, either the farmer fails or he does not, depending on

the outcome of price. The probability of failure is the probability of the low price being realized, which in this example is 50%.

An important aspect of this model to note is that, except at the boundaries of these regions, expending incrementally any more or less effort will not affect the farmers probability of failure; it will only increase or decrease his benefits from farming. One may set, without loss of generality, the nonfarm utility level to zero, $I = 0$.

Consistent with the condition cited above, the objective function may then be represented in one of three ways, depending on whether the farmer's effort makes the probability of failure one, one-half, or zero:

$$(12a) \quad \mu 2e^{1/2} + (1 - e) - f \quad \text{if } \pi = 1, \text{ or } e^{1/2} < \frac{f}{2u_h\mu}$$

$$(12b) \quad V = \frac{\mu 2e^{1/2} + (1 - e) - f}{1 - .5\beta} \quad \text{if } \pi = .5, \text{ or } \frac{f}{2u_h\mu} \leq e^{1/2} < \frac{f}{2u_l\mu}$$

$$(12c) \quad \frac{\mu 2e^{1/2} + (1 - e) - f}{1 - \beta} \quad \text{if } \pi = 0, \text{ or } \frac{f}{2u_l\mu} \leq e^{1/2}$$

Figure 1 shows one possible set of values of the function V . The concave lines show the values of the objective function for given levels of π . That is, the lowest curve represents expression (12a) over all values of effort, the middle curve represents expression (12b), and the highest curve represents expression (12c). The heavily drawn lines show the objective function taking π into account for a specific pair of price outcomes; these lines represent the set of possible choices of effort open to the farmer. For the case shown in the figure, optimal effort is where

$$(13) \quad e^* = \left[\frac{f}{2u_l\mu} \right]^2;$$

that is, optimal effort is chosen such that the probability of failure is zero. This illustrates the danger of taking observed probabilities of failure as exogenous to the farmer's supply decisions. Here there is no chance of failure, but the level of effort chosen is away from the point of "efficiency," ($e = \mu^2$), which would be optimal if risk of failure were irrelevant to decisions.

Optimal effort is conditional on regions in which expected price may fall. Optimal supply over expected price is graphically illustrated in figure 2. The farmer may not choose to be on a portion of the supply curve where $\pi = 1/2$, instead either choosing a supply where $\pi = 0$,

or where $\pi = 1$. The downward sloping portions of the supply curve are the regions of expected price where the farmer is in survival mode. The effect of eliminating price variability, abstracting from equilibrium effects, is illustrated in figure 2. Consider an expected price of $\bar{\mu}$. Eliminating variance (i.e., setting $u_l = u_h$) yields an optimal supply of $\bar{y}^* = 2\bar{\mu}^2$.

Now consider the market equilibrium. A stable, long-run equilibrium is an expected market price, μ_e , a level of effort e_e^* , and an expected supply \bar{y}_e^* , such that the number of producers is constant (i.e., $\pi = 0$), and where

$$(14a) \quad \mu_e = a[\bar{y}_e^*]^{-b}$$

$$(14b) \quad \bar{y}_e^* = 2e_e^{*1/2}$$

$$(14c) \quad e_e^* = e^*(\mu_e).$$

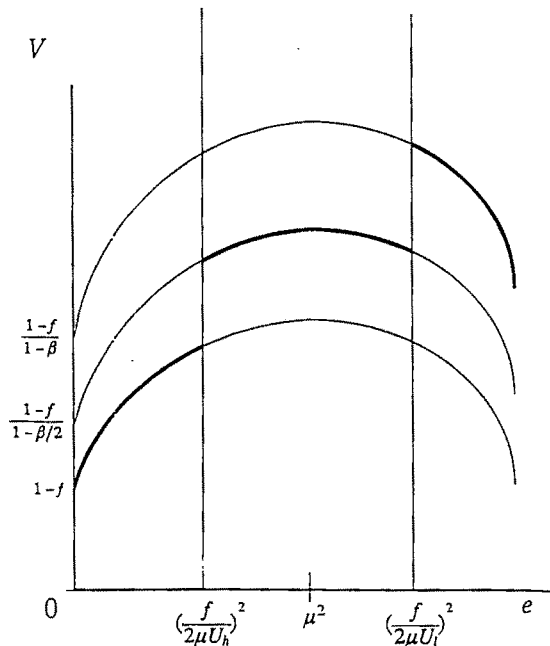

Figure 1. Values of the objective function over effort

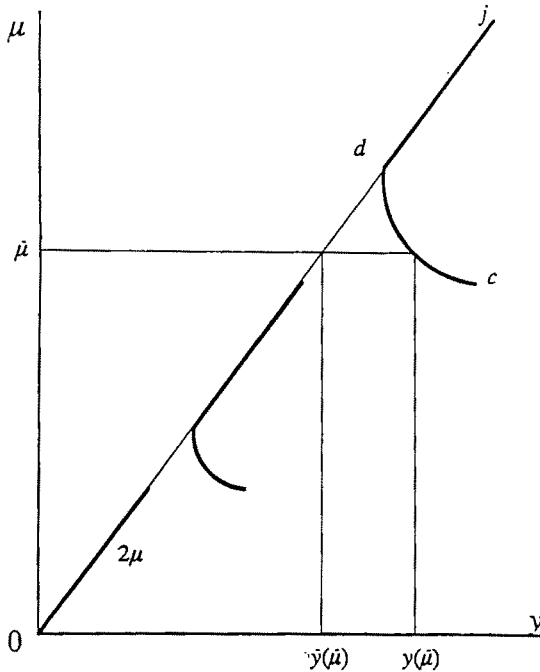

Figure 2. Optimal supply over expected price

Equation (14a) represents market equilibrium, (14b) represents the optimal expected supply given the optimal choice of effort, and (14c) represents the rational-expectations equilibrium where optimal effort is consistent with the equilibrium expected price. Stability implies that equilibrium price falls along the segments cd and dj on the supply curve in figure 2. The most interesting case is where the farmer is in survival mode but $\pi = 0$; that is, on segment cd of figure 2.

For a survival mode equilibrium to exist, expected price must be such that

$$(15) \quad \mu_e < \left[\frac{f}{2u_l} \right]^{1/2}.$$

In this case

$$(16) \quad \mu_e = a^{1/1-b} \left[\frac{f}{u_l} \right]^{-b/1-b}.$$

For an inelastic demand curve ($b > 1$), the conditions for survival-mode equilibrium are given by

$$(17) \quad \frac{f}{u_l} < 2^{1-b/1+b} a^{2/1+b}.$$

In fact, for all cases of demand, the above

condition is simply that which provides for the standard (nonsurvival-mode) equilibrium. That is, if a survival-mode equilibrium exists, then a conventional one does also. A conventional equilibrium exists where

$$(18) \quad \mu_e = (2a)^{1/1-b}.$$

An elastic demand may also yield a stable, survival-mode equilibrium; but, if one does not exist, then a conventional one would not exist as well. [The inequality in expression (18) above is reversed.] This leads to the idea of an overproduction trap. For both inelastic and elastic demands, survival-mode equilibria may exist. But only in the former case is one justified in using the term trap. In the latter case, survival mode arises only because of the objectives of farmers. In the inelastic-demand case, survival mode exists because of the objectives of farmers and the accident of expectations consistent with survival mode. Farmers are trapped by their rational expectations; without altering farmers' objectives, a conventional equilibrium may be attained.

Empirical Application

The preceding sections have discussed the influence of human-capital asset fixity on production decisions. This section empirically addresses farm production based on the conceptual model. First, even under risk neutrality the usual assumptions underlying the use of cost and profit functions are inapplicable in this case because the marginal-product-equals-price rule does not hold. Therefore, even if one used only disaggregated data, the conventional correlations of cost shares, for example, with factor prices would not represent production technology as standard application of duality theory would suggest. The difficulty is that marginal products are set equal to effective prices, which are unobserved. These effective prices are the observed prices adjusted by other factors reflecting the influence of the discrete difference between on-farm and off-farm utility and the probability of failure.

In standard applications, there are estimable equations for a production function (or cost, or profit) function and each marginal condition. If there are n choice variables with associated prices, the standard application would have $n + 1$ equations from which to estimate the parameters representing the production technology (n input demands, one output supply). One may solve n input choice variables for n prices, all of which

can be observed. In the nonstandard case described above, however, one can solve only for the choice variables in terms of the n prices and two price-adjustment factors, $1/(1 + \theta)$ and $(1 + \theta \mu/p_d)/(1 + \theta)$ from equations (8a) and (8b). Nevertheless, the marginal rates of technical substitution between inputs with common adjustment factors are dependent only on observable prices. Therefore, at best, $n - 2$ choice variables can be solved in terms of observable prices and two inputs associated with different adjustment factors. And one can obtain $n - 1$ equations from which to estimate production function parameters ($n - 2$ input demands, one output supply). This is not surprising, because this model introduces at least two additional unknowns into the choice problem. Under risk neutrality, besides the parameters defining technology, the true cost ($\bar{U} - I$) of leaving farming in any period is unobserved, as is the true probability of failure as a function of farm decisions. In order to estimate the production function parameters, unconditioned on the on-farm/off-farm utility difference and the failure probability, one must allow for the influence of these two additional unknowns through some similar number of observables.

To illustrate the conceptual and theoretical models above, we examine corn production in Illinois. This study estimates a per-acre production function, assuming a particular production function and utilizing the plausible restrictions on parameter estimates implied by the behavior model of a profit-maximizing farmer. Of course, other models also could result in production inefficiency, defined here as a wedge between marginal products and observed prices. The empirical analysis tests whether the adjustment factors driving a wedge between marginal products and prices, move in the direction implied by the conceptual model of input decisions under risk. Specifically, the empirical model tests whether or not input choices approach productive efficiency as farm size increase and over time (as farming is hypothesized to grow more integrated into the larger economy). Additionally, in recognition of the widespread farmer use of government programs and their influence on risk and farm decisions, the analysis examines to what degree programs affect the deviation of input choice from productive efficiency.

The empirical analysis takes four inputs (in per acre amounts) to a Cobb-Douglas production function. Consistent with the conceptual model, the inputs are separated into those that must be paid for immediately, fertilizer and hired

labor, and those that may go unpaid, farm family labor and physical capital, represented by machinery use. In order to reduce the scope of the problem, the possible influence of other crops is ignored—both in the usual joint-production sense, and, more importantly, in the sense of choosing a portfolio. The data are taken from *Summaries of Illinois Farm Business Records* from 1971 to 1979. This period was regarded as relatively prosperous for midwestern corn producers, with few downturns. Indeed, parts of this period were considered “boom times,” with many producers taking on greater debt consistent with a decreased perception of risk of farm failure. The period’s comparative prosperity, in marked contrast to the following years of the early 1980s, would tend to work against observing any influence of failure risk on input decisions. The data are averages of farm characteristics, production levels, factor expenses, and labor employed for farms in particular size ranges and regions. Price data are from the *Summaries*, the Department of Agriculture’s *Agricultural Statistics*, and the Commodity Research Bureau’s *Commodity Year Book*.

Yield is represented by Y , and input levels by X_i ; where $i = 1$ denotes fertilizer, $i = 2$ hired labor, $i = 3$ family labor, and $i = 4$ machinery. The W_i represent prices associated with the inputs, and the α_i represent associated elasticities to be estimated. We assume risk neutrality of farmers and that output price is independent of output. The March quote of the December futures contract for corn represents the expected output price. Denote this expected price by μ . The model also includes as shift variables the amount of corn acreage (Z_1) to account for a scale effect, and the average soil quality of the farm (Z_2). (See the *Summaries* for a definition of this variable.)

The production function is represented as

$$(19) \quad \ln Y = \tilde{\alpha}_0 + \sum_{i=1}^4 \alpha_i \ln X_i + \sum_{j=1}^2 \beta_j \ln Z_j.$$

From the general first-order conditions given by expressions (9a) and (9b), the marginal conditions for optimization are

$$(20a) \quad \frac{\mu Y}{W_i X_i} \alpha_i = \rho_1 \quad i = 1, 2,$$

$$(20b) \quad \frac{\mu Y}{W_j X_j} \alpha_j = \rho_2 \quad j = 3, 4,$$

where ρ_k , ($k = 1, 2$) represents the unknown adjustment factors associated with the two types of inputs. The marginal product restrictions within each input group are

$$(21a) \quad X_2 = \frac{\alpha_2}{\alpha_1} \frac{W_1}{W_2} X_1,$$

$$(21b) \quad X_4 = \frac{\alpha_4}{\alpha_3} \frac{W_3}{W_4} X_3.$$

Therefore, one can specify the system of equations

$$(22a) \quad \ln Y = \alpha_0 + \alpha_1 \ln X_1 + \alpha_2 \ln \frac{W_1 W_1}{W_2} + \alpha_3 \ln X_3 \\ + \alpha_4 \ln \frac{W_3 X_3}{W_4} + \beta_1 \ln Z_1 + \beta_2 \ln Z_2 + u_1$$

$$(22b) \quad \frac{W_2 X_2}{\mu Y} = r_1 \frac{W_1 X_1}{\mu Y} + u_2$$

$$(22c) \quad \frac{W_4 X_4}{\mu Y} = r_3 \frac{W_3 X_3}{\mu Y} + u_3,$$

where $r_1 = \alpha_2/\alpha_1$, and $r_3 = \alpha_4/\alpha_3$. These three equations may be estimated using a seemingly unrelated regression technique that imposes nonlinear restrictions on the coefficients.⁸

The estimates of the production function elasticities are reported in table 2. The estimated production elasticities with respect to the inputs are positive and of plausible magnitude. One noteworthy result is the large difference between the elasticity of family labor and that of hired labor. Another result to note is the sign and magnitude of the coefficient on acreage under corn, indicating a positive scale effect. The per-acre production function, however, exhibits decreasing returns.

Of particular interest is how the adjustment factors (ρ_i) are influenced by non-input variables. In order to investigate this, assume that the adjustment factors may be represented in the following manner:

$$\rho_i = \frac{\mu Y}{W_i X_i} \alpha_i = a_i + b_i S + c_i T + d_i D \\ + e_i M + u_{1i} \quad i = 1, 2$$

Table 2. Estimates of Production Elasticities

Variable	Coefficient	Estimate	<i>t</i> -statistic
Constant	α_0	3.0282	6.0490
Fertilizer	α_1	0.1015	1.4472
Hired labor	α_2	0.0174	1.4367
Family labor	α_3	0.1407	4.3126
Machinery	α_4	0.2280	4.3200
Corn acreage	β_1	0.2555	3.5311
Soil quality index	β_2	0.0085	11.773

$$\rho_2 = \frac{\mu Y}{W_j X_j} \alpha_j = a_2 + b_2 S + c_2 T + d_2 D \\ + e_2 M + u_{2j} \quad j = 3, 4,$$

where S represents farm size in gross acreage, T a time index, D the percent tillable land under program diversion, and M the proportion of off-farm income to total income.

From the discussions in the previous sections, one expects that as farm size grows the adjustment factors approach one, falling ($b_1 < 0$) in the case of fertilizer and hired labor ($i = 1, 2$), and increasing ($b_2 > 0$) in the case of family labor and machinery ($j = 3, 4$). These effects reflect that the fixed costs of farming which must be covered in order for the farmer to remain in agriculture do not grow in proportion with farm size. The larger operations relative to the smaller ones spread these fixed costs over a greater number of acres, and this optimally sets marginal products closer to observed factor prices. The time index, T , reflects an overall improvement in alternatives for farm family labor; growing integration of the farm sector and the larger economy, and other structural changes that promote stricter profit maximizing (that is, $c_1 < 0$ and $c_2 > 0$).

One variable of special concern indicating the integration of farm labor into other sectors is the relative importance of off-farm income to the total farm family income. As the family grows less dependent on uncertain production-based returns and more dependent on sure, off-farm sources, the farmer places less weight on avoiding poor crop revenues ($e_1 < 0$ and $e_2 > 0$). This effect would best be measured by the proportion of off-farm income relative to total income for specific farm families. This set of data was unavailable. Instead the model takes the proportion of total nonfarm income earned by U.S. farmers relative to total income from both farm and nonfarm sources. Thus, the data reflect only

⁸ One potential difficulty with the SUR approach is the possible simultaneity of the representative inputs and the level of production.

aggregate changes in off-farm income to commercial enterprises.⁹

The program variable, D , reflects farmer's response to government payments. Three effects from government programs can be identified. First, programs may reduce the risk of failure and thereby promote efficiency. Second, programs may increase the opportunity cost of leaving farming, at the same time reducing failure risk, and thereby promote inefficiency. Third, programs may increase the effective output price through target prices. Despite these three distinct effects, one may be able to detect which has the greater influence by examining the pair of coefficients d_1 and d_2 . If the first effect predominates, then the signs of the coefficients on D are expected to be positive for family labor and machinery ($d_2 > 0$), and negative for fertilizer and hired labor ($d_1 < 0$). If the second effect predominates, then the signs on this coefficient will be reversed ($d_1 > 0$ and $d_2 < 0$). Finally, if the third effect predominates, then the signs on both coefficients will be negative for both equations ($d_1 < 0$ and $d_2 < 0$).

Using the first-order conditions, specify four additional equations:

$$(23a) \quad \frac{\rho_1}{\alpha_1} = \frac{\mu Y}{W_1 X_1} = \frac{a_1}{\alpha_1} + \frac{b_1}{c_1} S + \frac{c_1}{\alpha_1} T + \frac{d_1}{\alpha_1} D + \frac{e_1}{\alpha_1} M + \frac{u_{11}}{\alpha_1}$$

$$(23b) \quad \frac{\rho_1}{\alpha_2} = \frac{\mu Y}{W_2 X_2} = \frac{a_1}{\alpha_2} + \frac{b_1}{\alpha_2} S + \frac{c_1}{\alpha_2} T + \frac{d_1}{\alpha_2} D + \frac{e_1}{\alpha_2} M + \frac{u_{12}}{\alpha_2}$$

$$(23c) \quad \frac{\rho_2}{\alpha_3} = \frac{\mu Y}{W_3 X_3} = \frac{a_2}{\alpha_3} + \frac{b_2}{\alpha_3} S + \frac{c_2}{\alpha_3} T + \frac{d_2}{\alpha_3} D + \frac{e_1}{\alpha_3} M + \frac{u_{23}}{\alpha_3}$$

$$(23d) \quad \frac{\rho_2}{\alpha_4} = \frac{\mu Y}{W_4 X_4} = \frac{a_2}{\alpha_4} + \frac{b_2}{\alpha_4} S + \frac{c_2}{\alpha_4} T + \frac{d_2}{\alpha_4} D + \frac{e_1}{\alpha_4} M + \frac{u_{24}}{\alpha_4}$$

These equations may be estimated using SUR with linear cross-equation restrictions. The restrictions are obtained from estimates of the production elasticities. For example, the coefficients on the national off-farm income variable

for the cash-draining inputs, say e'_1 and e''_1 , are restricted such that $e'_1 = \alpha_2/\alpha_1 e''_1$.¹⁰

The estimates of the coefficients for the adjustment-factor equations are reported in table 3. The coefficients on farm size in the adjustment-factor equations support the conclusions of the conceptual model. Over farm size the adjustment factor falls for fertilizer and hired labor and increases for family labor and machinery. The coefficients are both significantly different from zero with a degree of confidence greater than 95%. The coefficients are also of the same magnitude, although of different sign (as expected), suggesting that the effect of farm size on the deviation from strict profit maximization is roughly symmetric with respect to decisions regarding both types of inputs. Similarly, the coefficients on the variable measuring the importance of off-farm income are of expected sign. The greater the proportion of off-farm income, the less the marginal products of fertilizer and hired labor exceed their observed factor prices and the less the marginal products of family labor and machinery fall short.

The coefficient on the off-farm income variable, however, is insignificantly different from

⁹ A reviewer notes that off-farm income in some cases could be approximated by aggregate data by sales classes. Such class data, however, are not immediately applicable here. The farm sizes here for the most part are of the commercial class, although not exclusively. Moreover, the farm sizes used change over time. The results should be interpreted in this light, specifically as if the relative off-farm income across farms was a constant, and the data reflect only common changes in levels.

¹⁰ There are two noteworthy potential problems with this estimation method. First the restrictions rely on estimates of the production elasticities. Interpretation of the standard errors must rely on asymptotics and caution is advised. Second, the error terms in these four equations above may not be independent of the errors in the equations representing the production relations. Ideally, a larger seven-equation system would be estimated, production relations and adjustment factors together.

Table 3. Coefficient Estimates for the Adjustment Factors

Variable	Coefficient	Estimate	t-statistic
Cash-draining inputs			
Constant	$a'_1 = \frac{a_1}{\alpha_1} = \frac{\alpha_2}{\alpha_1} a''_1$	17.639	5.580
Gross acreage	$b'_1 = \frac{b_1}{\alpha_1} = \frac{\alpha_2}{\alpha_1} b''_1$	-0.0095	-10.972
Time index	$c'_1 = \frac{c_1}{\alpha_1} = \frac{\alpha_2}{\alpha_1} c''_1$	0.5189	3.549
Percent tillable land	$d'_1 = \frac{d_1}{\alpha_1} = \frac{\alpha_2}{\alpha_1} d''_1$	0.2386	2.838
Ratio off-farm to total income	$e'_1 = \frac{e_1}{\alpha_1} = \frac{\alpha_2}{\alpha_1} e''_1$	-2.5203	-0.418
Non-cash-draining inputs			
Constant	$a'_2 = \frac{a_2}{\alpha_3} = \frac{\alpha_4}{\alpha_3} a''_2$	-6.457	-2.592
Gross acreage	$b'_2 = \frac{b_2}{\alpha_3} = \frac{\alpha_4}{\alpha_3} b''_2$	0.0133	19.491
Time index	$c'_2 = \frac{c_2}{\alpha_3} = \frac{\alpha_4}{\alpha_3} c''_2$	-0.2959	-2.566
Percent tillable land	$d'_2 = \frac{d_2}{\alpha_3} = \frac{\alpha_4}{\alpha_3} d''_2$	-0.3298	-4.975
Ratio off-farm to total income	$e'_2 = \frac{e_2}{\alpha_3} = \frac{\alpha_4}{\alpha_3} e''_2$	24.323	5.115

ing off-farm income affects the utilization of the different types of inputs in an asymmetric way. Off-farm income lessens the overuse (relative to strict profit maximization) of family labor and machinery but has little if any effect on discouraging the underuse of the other inputs.

The time index represents all variables other than off-farm income that would measure the degree of integration of farming with the rest of the economy. The coefficients on this composite variable suggest that, for a given farm size, dependence on farm income, and degree of program participation, production decisions have been deviating further from pure profit maximization. These results are somewhat surprising in light of accepted wisdom that agriculture is in transition to greater integration with the rest of the economy. First, recall that the data are for a fairly short period of time, between 1971 and 1979. Second, the results for the time variable are supported at least in part by Vasavada's work on the measurement of excess inputs. Using a dynamic adjustment model, he concludes that for aggregate levels of labor and capital,

surpluses have shown a marked tendency to decline over a longer period of time (since 1948). During the 1970s, however, his results demonstrate a decline followed by an upswing in input-surplus indices. Troughs occur in 1972 for capital and 1974-75 for labor.

Finally, the coefficients on the program variable are of opposite signs for the two adjustment-factor equations and support the conclusion that government programs exacerbate the deviation from production efficiency.

Concluding Comments

The analytical and empirical results of this paper offer some insight into farmer behavior under risk of failure. A farmer cannot purchase complete insurance against such a risk. In addition to other responses (e.g., crop insurance, access to credit reserves), the farmer would seek to mitigate against this risk by deviating in his production decisions from what is optimal from a simple expected-profit-maximizing case. Production factors with immediate cash outlay tend to have higher effective prices than without the risk because part of their cost must be measured in the contribution to increasing the probability of failure. The marginal products of these factors are set higher than observed prices would optimally warrant. Conversely, factors that may be delayed in cash expenditure tend to have lower effective prices for the opposite reason, and their marginal products are set lower than observed prices warrant.

Factors of the last type are of particular interest because their contribution to aggregate capacity may be of greatest significance. Farm-operator labor, or farm family labor, tends to be overutilized at the expense of non-cash-generating alternatives (e.g., leisure time). Improving opportunities for off-farm income would encourage the farmer to use operator labor in a similar manner to hired labor. Physical capital, including aspects of land quality and long-term productivity, owned by the farmer is treated in the same way. The conceptual analysis suggests that during periods when farmers face higher probability of failure and the difference between on-farm and off-farm utility is larger, farmers would tend rationally to increase the deterioration of their resources.

This paper also offers an empirical investigation of corn production in Illinois. This is done in order both to demonstrate the applicability of the conceptual model and to substantiate certain

conclusions that can be drawn regarding the degree of deviation from simple profit maximization. Conventional estimation of dual functions, such as those of cost and profit, is unwarranted in the presence of risky adjustment costs. Nevertheless, the theory does admit certain restrictions to an estimable system of supply and factor demands, from which one can use output- and input-price data in the estimation of production technology. In addition to prices as explanatory variables, levels of a certain number of representative inputs (in this study, two) must be used with a corresponding reduction in the number of estimable equations. The estimation results indicate that larger farms deviate less from production efficiency than do smaller farms, where production efficiency is defined relative to strict profit maximization; and that the lesser the reliance on farm income as opposed to off-farm income, the greater the production efficiency. Over the period of time studied, however, farmers have been moving further from setting marginal products equal to observed prices.

Valuing the Multidimensional Impacts of Environmental Policy: Theory and Methods

John P. Hoehn

A theoretically consistent framework is developed for valuing the multidimensional impacts of environmental policy. Conventional benefit estimates are shown to be biased because of the presence of substitution and complementarity effects in valuing policy impacts. Procedures are developed for implementing a valid framework. Consistent with theory, empirical results indicate significant substitution effects in valuing environmental conditions across different geographic regions.

Key words: air quality, benefit cost analysis, contingent valuation, environmental policy, national parks, nonmarket valuation.

Environmental management requires tradeoffs across different environmental services and different user groups. Management policy is inherently multidimensional. A typical policy change is not simply to provide more or less of a single environmental characteristic but a decision as to what package or set of characteristics to provide.

The multidimensional nature of environmental policy has important implications for valuing policy change. As policy changes the package of environmental services, individual users make substitutions across a changing opportunity set. These substitutions affect the value that individuals place on both the overall policy package as well as its components.

Natural resource economists have been aware of the impact of substitution on resource valuations for some time. In the early 1970s, Burt and Brewer began the development of methods for valuing the attributes of a system of recreation sites. Knetsch discussed the problem of valuing existing recreational facilities that are displaced by a new recreational investment. Rosenthal showed the empirical biases that result when substitute prices are omitted from a travel cost model.

John P. Hoehn is an associate professor, Department of Agricultural Economics, Michigan State University.

Support from the U.S. Environmental Protection Agency and the Michigan Agricultural Experiment Station is gratefully acknowledged.

The author benefited from the referees' comments and discussions with Alan Randall, Richard Carson, Robert Mitchell, James Oehmke, and John Stoll.

The valuation concepts developed in the context of local recreation sites have not been extended to the general problem of valuing the benefits and costs of a multidimensional environmental policy. Instead, conventional benefit cost procedures tend to proceed on a piecemeal basis. Each element of a multiple impact policy is evaluated independently, as if it were the only element to be changed by policy. The conventional approach ignores any substitution or complementarity effects that may occur. A total valuation is obtained by summing across the independent component valuations.

It is clear that the conventional benefit cost design is conceptually and empirically flawed. Hoehn and Randall show that conventional procedures overstate the net benefits of a large, multidimensional policy change. Hoehn and Randall find that the conventional approach actually misidentifies detrimental policies as potential Pareto improvements. The results of Braeutigam and Noll; and Majid, Sinden, and Randall indicate a significant empirical divergence between the conventional and valid valuation approaches.

This paper examines a valid framework for valuing the multidimensional impacts of environmental policy. The first section of the paper outlines both the conventional and valid valuation designs.¹ The second section examines the prospect of substitution and complementarity between policy components. The third section

¹ Hof et al. consider similar issues for a firm's cost structure.

derives procedures for implementing the valid design with contingent valuation. The final section estimates valid bid functions and tests the empirical significance of substitution in valuing regional environmental quality conditions.

Conventional and Valid Designs

This section examines the valuation of environmental impacts brought about by a change in public policy. Policy impacts include a range of environmental effects. Impacts may include changes in physical resource flows, characteristics of the legal and social environment, or altruistic services such as those leading to existence value.²

Valuing a Single Impact Policy

The value of an environmental change stems from the tradeoffs a household is willing to make between (a) a change in an environmental service and (b) other desirable goods and services. Analytically, these tradeoffs are summarized in terms of a household's expenditure function. The expenditure function is a basic tool in defining the Hicksian measures of value.

Household preferences across market goods, $x = (x_1, \dots, x_L)$, and environmental services, $q = (q_1, q_2)$, are described by a utility function, $u = u(x, q_1, q_2)$, that is strictly increasing, continuous, and strictly quasi-concave. Given income, m , market prices, p , and access to environmental services, q , the level of well-being attained by a household is described by an indirect utility function, $v(p, q_1, q_2, m)$. At initial income, m^0 , and initial environmental quality, $q^0 = (q_1^0, q_2^0)$, initial utility is $u^0 = v(p, q_1^0, q_2^0, m^0)$.

The household's expenditure function is

$$(1) \quad e(q_1, q_2, u) = \min_x px \quad \text{s.t. } u(x, q_1, q_2) \geq u$$

where p is left implicit. Given the assumptions on utility, $e(q_1, q_2, u)$ is strictly decreasing and convex in q (Mäler). At initial environmental quality, q^0 , initial income maintains initial utility, $m^0 = e(q_1^0, q_2^0, u^0)$.

The Hicksian compensating measure of benefit, HC , is the amount of income, paid or re-

ceived, that would leave a household at a pre-policy level of well-being at the post-policy level of environmental quality. For a single impact policy that changes q_1 from q_1^0 to q_1^1 , HC is

$$(2) \quad HC(q_1^1, q_2^0; q^0) = m^0 - e(q_1^1, q_2^0, u^0).$$

where $m^0 = e(q_1^0, q_2^0, u^0)$. Equation (2) is the mathematical structure that underlies the Bradford bid curve (Bradford; Brookshire, Randall, and Stoll).

A Bradford bid curve analogous to equation (2) is shown in figure 1. The bid curve has a value of zero at the initial level of environmental quality. For a policy change from q_1^0 to q_1^1 that is beneficial to a household, the expenditure required to sustain the initial level of well-being declines and HC is positive. In this case, HC measures a household's willingness to pay (WTP). For a detrimental policy such as the change from q_1^0 to q_1^2 , the expenditure required to sustain initial utility is greater after the policy change and HC is negative. HC times minus one is the willingness to accept compensation (WTA).

The Evaluation of a Multidimensional Policy

A multidimensional policy results in the simultaneous change of two or more environmental services. This section compares the structure of a conventional evaluation of a multidimensional policy with a valid design.

The conventional approach values a multidimensional policy by independent valuation and summation (IVS). IVS values each of the im-

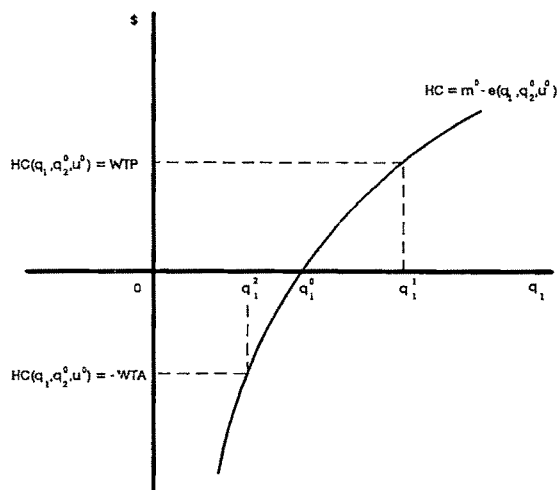

Figure 1. A Bradford bid curve

² Randall and Stoll discuss economic motivations for existence value.

pacts of a multidimensional policy as if each were a single impact policy. The independent valuations are added up to obtain an aggregate valuation.

For a two-element change from (q_1^0, q_2^0) to (q_1^1, q_2^1) , the *IVS* valuation is

$$(3.1) \quad IVS(q^1; q^0) = m^0 - e(q_1^1, q_2^0, u^0),$$

$$(3.2) \quad + m^0 - e(q_1^0, q_2^1, u^0).$$

The *IVS* approach fails to account for the aggregate impact of the policy change from q^0 to q^1 . Each of the policy impacts is evaluated with the other environmental parameter held constant at its initial level.

For a multiple impact policy, *HC* is the amount of income paid or received that would leave a household at the initial level of utility subsequent to the multiple impacts of policy. For the vector change from q^0 to q^1 , *HC* is

$$(4) \quad HC(q^1; q^0) = m^0 - e(q_1^1, q_2^1, u^0);$$

HC is unique and encompasses the impact of a multidimensional policy in a single, one-step valuation. In principle, contingent valuation can be used to implement equation (4) as a one-step, holistic valuation.

A disaggregated valuation is derived from equation (4) using a valuation path that begins at (q_1^0, q_2^0) and ends at (q_1^1, q_2^1) . The path may be either sequential or simultaneous. A sequential path shifts policy components one at a time from their initial to post-policy level. Using a sequential path that changes (q_1^0, q_2^0) to (q_1^1, q_2^0) , first, and shifts (q_1^1, q_2^0) to (q_1^1, q_2^1) , second, *HC* is

$$(5.1) \quad HC(q^1; q^0) = m^0 - e(q_1^1, q_2^0, u^0)$$

$$(5.2) \quad + e(q_1^1, q_2^0, u^0) - e(q_1^1, q_2^1, u^0).$$

The sequential valuation indicates how a valid disaggregate design accounts for the impact of the overall policy as well as its respective components. Line (5.1) values the change in q_1 with q_2 held constant at its initial level. Line (5.2) values the change in q_2 with q_1 at its post-policy level. Since the second term on the right-hand side of line (5.1) cancels with the first term in line (5.2), the sequenced valuation reduces to a quantity that is identical to equation (4)—the aggregate valuation.

Although the aggregate valuation is unique, the sequenced component valuations vary with the selected path. With a different valuation path—one that changes q_2 first and q_1 second—the component valuations in equation (5) would

be conditioned on a different level of the other environmental service. A change in conditioning variables changes the sequenced valuations.³

A simultaneous path values each policy component as the overall policy vector changes from q^0 to q^1 . A disaggregate valuation corresponding to a simultaneous path is⁴

$$(6.1) \quad HC(q^1; q^0) = \int_{q^0}^{q^1} [\partial e(q_1, q_2, u^0) / \partial q_1] dq_1$$

$$(6.2) \quad + \int_{q^0}^{q^1} [\partial e(q_1, q_2, u^0) / \partial q_2] dq_2,$$

where lines (6.1) and (6.2) each evaluate a derivative of the expenditure function, $\partial e(q_1, q_2, u^0) / \partial q_i$, $i \in \{1, 2\}$, as the overall policy shifts from its initial to its post-policy level. With the simultaneous path, both the aggregate and the component valuations are unique.

The valid component valuations may be estimated using either contingent valuation or a demand-based, weak complementarity method such as the travel cost or hedonic approach. A sequenced contingent valuation presents a sequence of changes and elicits a valuation at each step of the sequence. A simultaneous contingent valuation elicits the aggregate valuation, first, and then asks a respondent to partition the aggregate valuation into portions that are relevant to the respective components. Travel cost or hedonic demands are substituted directly into equations (5) or (6) by using the mathematical relationship between the expenditure function and weakly complementary demands.⁵

For a small number of policy impacts, the relationship between *HC* and *IVS* depends upon the extent of substitution, independence, or complementarity between policy components. Elements of q are substitutes, independent, or complements in valuation as the marginal valuation of q_i decreases, remains constant, or increases with an increase in q_j ; that is, as $\partial^2 HC / \partial q_i \partial q_j = - \partial^2 e / \partial q_i \partial q_j$ is negative, zero, or positive.

IVS overstates the valid valuation if environmental services are substitutes. With substitutes, line (5.1) is equal to (3.1) but line (5.2)

³ Conditioning variables may be viewed as part of the valuation context. The valuation context or frame plays a key role in psychological theories of valuation (Fischhoff and Furby).

⁴ The definition of a line integral leads directly to the simultaneous path.

⁵ Weak complementarity is detailed in Bockstael and Kling.

is less than line (3.2). Substitution implies that both lines in equation (6) are less than their counterparts in equation (3). With complementarity, the opposite effect occurs and *IVS* understates the aggregate and component valuations. *IVS* is equal to *HC* only if q_1 and q_2 are independent.⁶

WTP and *WTA* are each affected differently by substitution and complementarity. If a policy change is beneficial ($q_i^1 > q_i^0$), *HC* equals *WTP* and the impact of substitution and complementarity on *WTP* is identical to the impact on *HC*. If a policy change is detrimental ($q_i^1 < q_i^0$), *WTA* equals $-HC$. Because of the change in sign, the impact of substitution and complementarity on *WTA* is just the opposite of their effect on *HC*. With substitution, the *IVS* measure of *WTA* is less than the valid measure of *WTA*.

These effects on *WTP* and *WTA* result in distorted benefit cost outcomes when the *IVS* design is used. Suppose that, consistent with a potential Pareto improvement, benefits are measured using *WTP*, costs are measured using *WTA*, and net benefit is aggregate *WTP* minus aggregate *WTA*. If environmental services are substitutes, *IVS* overstates *WTP*, understates *WTA*, and overstates the net benefit of policy change. If they are complements, *IVS* understates net benefit. The *IVS* and *HC* net benefit measures are equivalent only when environmental services are independent in valuation.

The Prospect of Independence in Valuation

A valid benefit cost design imposes significant costs on practical policy evaluation. In addition to the challenge of valuing single components, a valid benefit cost design accounts for interactions between different components. These additional costs could be substantially reduced if independence were either predictable or routine.

Two valuation contexts suggest a strong pros-

pect of at least approximate independence. The first is a large number case that characterizes national planning problems where numerous agencies independently evaluate a large number of different policy proposals. In this case, the effects of substitution and complementarity may cancel out as the number of policy components—and *IVS* errors—becomes large.

Hoehn and Randall show that *IVS* errors do not cancel out in the large number case. Resource scarcity within an economy imposes a bound on the valid measure of benefits while the *IVS* outcome is unbounded. *IVS* is certain to overstate net benefits as the number of evaluations grows large.

The second policy setting involves a small number of policy components. This case is relevant to the internal planning problem of a single agency. Although a single agency may not have control of the overall policy agenda, it may still seek an accurate evaluation of its own program. This section examines the small number problem.

Hypotheses regarding the small number case are derived from the structure of individual choice and valuation. Substitution and complementarity appear to result from specific linkages in producing a subsistence or leisure activity that uses environmental services as inputs. The absence of a specific linkage in consumption may lead to independence in valuation.

The absence of a direct linkage in consumption is routinely expressed by an additively separable utility function,

$$u = \sum_{h=1}^H u_h(x, q_h),$$

where $q_h = (q_{h1}, \dots, q_{hI})$, $h \in \{1, \dots, H\}$, represents $H \times I$ different environmental services (Green, Deaton and Muellbauer). Environmental services q_h are additively separable from services q_g , $g \neq h$. As differentiation shows, the marginal utility of component q_{hi} is unaffected by a change in q_{gj} since $\partial^2 u / \partial q_{hi} \partial q_{gj}$ equals zero, $i, j \in \{1, \dots, I\}$. Environmental services that enter the same utility component, u_h , are not additively separable because $\partial^2 u / \partial q_{hi} \partial q_{hj}$ equals $\partial^2 u_h / \partial q_{hi} \partial q_{hj}$, which may be positive, negative, or zero.

Contrary to simple intuition, theorem 1 shows that independence in consumption leads to strict substitution in valuation.

THEOREM 1. *Let the preferences of a household be represented by a utility function such*

⁶ The component valuation of the change from q_2^0 to q_2^1 is

$$e(q_1^1, q_2^0, u^0) - e(q_1^1, q_2^1, u^0) = \int_{q_2^0}^{q_2^1} [-\partial e(q_1^1, q_2, u^0) / \partial q_2] dq_2,$$

where r equals zero to obtain line (3.2) and r equals unity to obtain line (5.2). If q_1 and q_2 are substitutes, the integrand evaluated at q_1^1 is smaller than the integrand evaluated at q_1^0 . Thus, line (5.2) is smaller than line (3.2). If q_1 and q_2 are complements, then the opposite conclusion holds. If the two are independent, lines (3.2) and (5.2) are equal. A similar analysis applies to equations (3) and (6). Psychologists have discussed these effects as an embedding phenomenon (Kahneman and Knetsch).

that (a) q_{hi} is additively separable from q_{gj} and (b) q_{hj} and q_{hk} are not additively separable. Assume that the utility components, u_h , are concave in x and that environmental services and market goods are gross complements, i.e., $\partial^2 u_h / \partial q_{hi} \partial x_n > 0$. The following properties hold for environmental services with nonzero valuations: (a) environmental services that are additively separable in utility are substitutes in valuation and (b) environmental services that are not additively separable in utility may be substitutes, complements, or independent in valuation.⁷

The theorem demonstrates that substitution effects in valuation are the rule rather than the exception. Substitution occurs consistently across all valuation contexts and arises because of the mathematical structure of constrained optimization. Substitution effects in valuation are certain if there is no direct utility linkage between environmental services. Complementarity and independence are possible only if a complementary linkage outweighs the substitution effect induced by constrained choice.

Two routine valuation contexts lead to additive separability and strict substitution. The first involves spatially separated activities. A household's use of a ski site in region h may be unaffected by its use of a ski site in region g . Fishing opportunities in region h may be unaffected by boating opportunities in region g . In a household production framework, each regional activity may be viewed as a different production process, $u_h(\cdot)$, that is separable in consumption. Regional environmental conditions enjoyed in separable activities are strict substitutes in valuation.

The second source of dominating additivity stems from uncertainty and the expected utility property. For example, suppose $h \in \{1, 2\}$ and that the enjoyment of q_1 or q_2 depends on some probabilistic event. The probability of enjoying q_1 and being without q_2 is π_1 , the probability of enjoying q_2 but going without q_1 is $(1 - \pi_1)$. The expected utility property implies that

$$(7) \quad u = \pi_1 u_1(x_1, q_1) + (1 - \pi_1) u_2(x_2, q_2),$$

where x_h represents market goods consumed in state h . The expected utility property introduces additive separability across mutually exclusive outcomes. Environmental conditions associated with different uncertain outcomes are substitutes in valuation.

Environmental valuations often involve the concept of option price. Because they are derived within an analogous expected utility framework, option prices may be sensitive to substitution effects. IVS estimates of option prices may be sensitive to substitution effects. IVS estimates of option price are likely to overstate the valid measure of benefits.

Estimating the Benefits of Complex Policy

Accurate evaluation of policy benefits requires procedures for implementing a valid benefit cost design. As indicated above, a valid design may use either contingent valuation or demand-based techniques such as the travel cost and hedonic approaches. Demand-based approaches that encompass substitution and complementarity effects are relatively well understood (Deaton and Muellbauer). This section focuses on empirical procedures for use with contingent valuation.

Contingent Valuation Alternatives

Contingent valuation (CV) is in theory adaptable to any level of a valid valuation design. The issue with contingent valuation is largely one of experimental design—of how to develop adequate value information at the least cost. In some cases, the valuation problem is simple. For instance, if the composition of a policy is predetermined, a single valuation question may be formulated consistent with equation (4). There is no need to disaggregate and value each of the components.

The valuation problem is typically more complex. An agency may have identified a candidate set of policy instruments but be uncertain as to the composition of a final policy. Benefit information is used to evaluate both the aggregate policy as well as the components. In this case, one might attempt to identify all possible combinations of the candidate impacts and then evaluate each holistically according to equation (4). An all-inclusive approach is likely to be costly.

An econometric approach reduces the cost of exploratory valuation by extracting a maximum amount of information from a sample of value data. The first step is to draw a representative sample of policy scenarios and to elicit contingent valuations for each scenario as suggested by equation (4). The functional relationship underlying equation (4) is then estimated in a man-

⁷ A proof of theorem 1 is available upon request to the author.

ner analogous to those used with multiproduct cost functions (Baumol, Panzar, and Willig). The estimated relationship is a multidimensional Bradford bid function that gives the benefits associated with any combination and level of policy components.

There are three considerations in selecting a functional form for equation (4). First, the predetermined variables should enter the bid functions in a manner consistent with theory. This requires that the bid function be equal to zero when environmental quality is held constant at the initial level. Socioeconomic variables should also enter the functions so that the initial conditions hold. Variables representing environmental quality should be permitted to take on any sign.

Second, the convexity of the expenditure function in q implies a bid function that is concave in q . A concave bid function has a Jacobian that is negative semidefinite. Since the concavity restriction results from a convenient but not necessary utility assumption, a functional form should be flexible enough to allow either concavity or convexity. Such flexibility permits an empirical test of concavity.

Third, the function should admit either substitution, complementarity, or independence between different pairs of amenity services. Neither the Cobb-Douglas nor the constant elasticity of substitution (CES) function satisfies this second criterion. The Cobb-Douglas and CES forms both impose qualitatively uniform effects across different pairs of amenities.

Functional Forms

Admissible empirical forms for the bid function are obtained using the approach used to derive flexible production and cost functions. This approach approximates the true functional form with a second-order Taylor-series expansion (TSE) (Gallant).⁸ The TSE parameters that measure pairwise interactions may take on any sign and socioeconomic variables can be entered in a manner consistent with the initial conditions. Environmental services may be amenities or disamenities.

A quadratic bid function is obtained by applying the TSE directly to equation (4). Before

expanding, however, two alterations are appropriate. First, to remove an unobservable utility term, $u^0 = v(q^0, m^0)$ is substituted into (4). Second, consistent with the household production literature, the utility and expenditure functions depend on the socioeconomic characteristics of a household, \bar{s} . With these changes, the quadratic specification is

$$(8) \quad HC(q^1; q^0) = m^0 - c(q_1^1, q_2^1, q^0, s),$$

where $c(q_1^1, q_2^1, q^0, s) = e(q_1^1, q_2^1, \bar{s}, v(q^0, \bar{s}, m^0))$ and $s = (\bar{s}, m^0)$.

Define the n th policy scenario, $n \in \{1, \dots, N\}$, as a set of ordered pairs, $\{(q_1^w, q_1^z), (q_2^w, q_2^z)\}$, where w and z are from a real interval that includes zero and one.⁹ For a sample of R respondents and N policy scenarios, a TSE taken about the initial values q^0 and the mean value of s , \bar{s} , results in

$$(9) \quad hc_{rn} = \alpha_0 + ds_r' \alpha_s + dq_n \beta + ds_r' A dq_n + dq_n' B dq_n + \epsilon_{rn},$$

where hc_{rn} is the r th respondent's valuation of the n th policy scenario; α_0 is a constant; $ds_r = (s_r - \bar{s})$ is a vector of differences between the r th respondent's characteristics, s_r , and \bar{s} ; α_s is conformable coefficient vector; $dq_r = [(q_1^w - q_1^0), (q_2^z - q_2^0)]$ is a vector of differences between the r th post-policy level of environmental quality and the initial environmental quality level; $\beta = (\beta_1, \beta_2)$ is a two-element coefficient vector; A is a coefficient matrix conformable to ds_r and dq_n ; $B = [b_{ij}]$, $i, j \in \{1, 2\}$, is a matrix of environmental interaction coefficients; and ϵ_{rn} is a statistical error term. With the independent variables in their differenced form, the coefficient β_h represents the marginal value of a change in q_h from q^0 .

The error ϵ_{rn} may be correlated across observations if multiple responses are obtained from individual respondents. In this case, ordinary least squares are not minimum variance estimators. Efficient estimates are obtained using generalized least squares procedures developed for panel data.

The quadratic function (9) is adaptable to requirements of economic theory. First, the expected value of hc_{rn} is equal to zero at the initial quality level if α_0 and α_s are equal zero. These

⁸ TSE forms are suitable to a local approximation of the true functional form. Global properties of flexible functional forms may be undesirable (Caves and Christensen).

⁹ The variables w and z allow one to describe sampling designs that include more than one policy scenario. In previous sections, w and z are unity.

restrictions on α_0 and α_s can be tested using routine statistical procedures.

Second, the quadratic permits either a concave or convex bid function. The quadratic is concave (convex) if B is negative (positive) semidefinite. Concavity (convexity) requires that the diagonal elements of B are nonpositive (non-negative) and the principal minors of $|B|$ alternate in sign (are non-negative). For two quality elements, this means that b_{ii} is nonpositive for concavity, b_{ii} is non-negative for convexity, and $|B| = b_{11}b_{22} - b_{12}^2$ is non-negative in either case.

Third, the quadratic equation (9) admits substitution, independence, or complementarity. Differentiation shows that environmental services are substitutes, independent, or complements as the asymmetric, off-diagonal terms in B , b_{ij} , $i \neq j$, are negative, zero, or positive.

The structure of a bid function precludes the derivation of a transcendental logarithmic (translog) function directly from equation (8). With a translog, the logarithm of a zero valuation is undefined.¹⁰ However, a semilogarithmic quadratic (semilog) form can be derived by taking a TSE about the logarithms of the right-hand-side variables in equation (8). The semilog quadratic specification is

$$(10) \quad hc_{rn} = \rho_0 + dls'_r \rho_s + dlq'_n \gamma + dls'_r C dlq_n + dlq'_n D dlq_n + v_{rn},$$

where ρ_0 is a constant; dls_r is a vector of differences between the logarithms of the elements of s_r and the logarithms of the elements of \bar{s} ; ρ_s is a conformable coefficient vector; $dlq_n = [\log(q_1^n) - \log(q_1^0), \log(q_2^n) - \log(q_2^0)]$ is the vector of differences between the logarithms of the n th post-policy level of environmental quality and of the initial environmental quality level; $\gamma = (\gamma_1, \gamma_2)$ is a two-element coefficient vector; C is a coefficient matrix conformable to dls_r and dlq_n ; $D = [d_{ij}]$, $i, j \in \{1, 2\}$, is a matrix of environmental interaction coefficients; and v_{rn} is an error term. Statistical properties of v_{nr} are analogous to those of ϵ_{rn} .

Equation (10) is adaptable to the restrictions of theory. Here, $E(hc_{rn})$ is equal to zero at the initial quality level if the estimated ρ_0 is equal to zero. The convexity restrictions on D and the form of interaction between environmental quality levels are analogous, at the point of approximation q^0 and \bar{s} , to those of equation (9).

Empirical Tests for Interaction

In this section, both the quadratic and the semilog bid functions are estimated. The estimated parameters are used to test the statistical significance of interaction effects in valuation.

Data for the empirical analysis came from a contingent valuation experiment conducted in Chicago, Illinois, during 1980 and 1981.¹¹ The experiment asked two sets of respondents to value changes in visual air quality in two different regions of the United States. The first sample of respondents was drawn from residents of Chicago in the summer of 1980. These respondents were asked to value improvements in air quality for Grand Canyon National Park. Respondents were read a narrative and shown photographs that represented the baseline conditions and the feasible improvements in visual air quality. Independent valuations were obtained for Grand Canyon air quality improvements of 40%, 83%, and 376%.

The second sample of respondents was drawn from Chicago residents in the spring of 1981. Three of the valuation questions posed to this set of respondents are of interest. First, respondents were read a narrative and shown photographs that represented two improvements of 100% and 233% in visual air quality for the Chicago metropolitan area. Independent valuations were obtained for each of these prospective improvements. Respondents were also read a narrative and shown the photographs representing the 83% improvement for the Grand Canyon. A final question valued a joint policy that proposed a 100% improvement for Chicago and an 83% improvement for the Grand Canyon.

By theorem 1, substitution effects are expected between the Chicago and Grand Canyon valuations. For a typical Chicago resident, future use of Grand Canyon improvements is likely to involve substantial uncertainty. Enjoyment of regional air quality conditions is also separated by both space and time. Both uncertainty and the spatial dimension suggest a hypothesis of substitution effects in valuation.

Before analyzing the data, valuations were screened to remove protest bids. Protest bids are zero valuations submitted by respondents who objected to the valuation procedure (Mitchell and Carson).

Table 1 lists the value data and sample characteristics for the 1980 and 1981 surveys. The independent valuations of Grand Canyon air

¹⁰ A translog form was derived from the dependent variable $(m^0 - HC)/m^0$. The translog proved intractable in testing and inferior in specification tests.

¹¹ Data collection procedures are detailed in Tolley and Fabian.

Table 1. Sample Value Data and Characteristics

Sample and Variable Names ^a	Mean	Standard Error
1980 Sample ^b		
Value of 40% improvement, G. Canyon (129)	\$58.8	1.0
Value of 83% improvement, G. Canyon (182)	\$82.7	0.95
Value of 376% improvement, G. Canyon (129)	\$128	2.2
Household income, \$1,000 (182)	\$28.1	0.10
Years of school attended (182)	14.1	0.17
Age in years (182)	41.0	0.12
Gender, male equals 0, female equals 1 (182)	0.637	0.0038
1981 Sample		
Value of 100% improvement in Chicago (71)	\$179	4.3
Value of 223% improvement in Chicago (71)	\$213	4.4
Value of 100% improvement in Chicago, and a 83% improvement in G. Canyon (71)	\$190	4.4
Household income, \$1,000 (71)	\$25.8	0.29
Years of school attended (71)	13.9	0.044
Age in years (71)	43.2	0.23
Gender, male equals 0, female equals 1 (71)	0.183	0.0056

^a Schooling, gender, and age statistics are for the respondent. The number of individuals in the sample is given in parentheses after each variable name.

^b In the 1980 sample, 129 respondents valued all three air quality improvements; 53 respondents valued only the 83% improvement.

quality range from \$58.8 to \$128 per year. The independent valuations of Chicago visibility range from \$179 to \$213 per year. The independent valuation of the 83% improvement in Grand Canyon visibility is \$82.7 per year. The same 83% change in Grand Canyon visibility is valued at only \$190 minus \$179 or \$11 per year when valued after a 100% change in Chicago visibility. The decrease in values due to the valuation sequence suggests strong substitution effects across regional air quality conditions.

Statistical tests for substitution were carried out using estimates of the quadratic and semilog bid functions. Table 2 reports the estimated equations. Variables used in the estimation were formulated in a manner consistent with equations (9) and (10). The dependent variable in all cases is the respondent's elicited valuation of the

described changes in visual air quality. The independent variables in quadratic form were entered in the manner described following equation (9). The independent variables in the semilog form were entered in the manner discussed following equation (10).

The independent variables are described in the first column of table 2. The first two variables listed, Grand Canyon Air Quality (*GCAQ*) and Chicago Air Quality (*CAQ*), measure the changes in air quality brought about by policy. The initial air quality level was normalized to one and the post-policy level was measured as a proportional change (e.g., 1.83, 2.0). Coefficients across the first two rows of table 2 measure elements of β for the quadratic and elements of γ for the semilog form.

The third, fourth, and fifth rows in table 2 give coefficients for the *B* and *D* matrices of, respectively, the quadratic and semilog functions. Rows three and four give the estimated coefficients for the diagonal terms. The fifth row states the off-diagonal terms. The remaining eight rows list the estimated elements of the *A* and *C* matrices that represent the interaction of air quality and socioeconomic characteristics.

Initial coefficient estimates were obtained using ordinary least squares (OLS). These are given in the second and fourth columns of table 2. Each of the air quality coefficients carries an intuitively consistent sign for environmental improvements that are amenities and substitutes. As air quality increases, a respondent's valuation increases but at a decreasing rate. The negative cross-product terms (fifth row) indicate substitution effects in the valuation of the two air quality variables.

Contingent valuation studies have generally ignored the inefficiency of OLS estimates when multiple valuations are obtained from the same individual respondents. An alternative is to specify the error structure as an error component model. An error component model allows for a nonzero covariance between a respondent's bids. With this model, the error terms in equations (9) and (10) are decomposed as $\epsilon_{rn} = \mu_r + \zeta_{rn}$ in the quadratic and $v_{rn} = \omega_r + \xi_{rn}$ in the semilog where $E(\mu_r^2) = \sigma_\mu^2$, $E(\omega_r^2) = \sigma_\omega^2$, and both ζ_{rn} and ξ_{rn} are uncorrelated across *r* and *n*. Generalized least squares (GLS) yields efficient estimates for the error component model (Judge et al. 1985, pps. 521–25).

The GLS estimates used for hypothesis testing are given in the third and fifth columns of table 2. The GLS data are identical to those used in the OLS equations. It is notable that the two

^a Variables are described in table 1.

^b Variables in the quadratic were formulated as in equation (9).

^c Variables in the semilogarithmic were formulated as in equation (10) except for the dummy variable gender. The dummy variable was entered without transforming it by a logarithm.

^d Columns labeled OLS were estimated using ordinary least squares. Columns headed GLS were estimated using the error components model described in Judge et al. (1985, pp. 521–25). A double pound sign (+) indicates that a coefficient is significantly different from zero at the 95% level for a one way test. A single (double) asterisk indicates that a coefficient is significantly different from zero at the 90% (95%) level for a two-way test. Standard errors are in parentheses. Estimates have 640 degrees of freedom.

sets of coefficients are very similar. As with the OLS estimates, air quality coefficients indicate that values increase at a decreasing rate with increases in air quality. The cross-quality interaction terms again suggest that regional air quality conditions are substitutes in valuation. Finally, consistent with the theoretical efficiency of the GLS estimator, the GLS estimated root mean square error is about 50% smaller than that of OLS for both the quadratic and semilog models.

Four sets of hypothesis tests were carried out with the GLS equations. First, with the derived functional forms, theory implies a bid function (1) without an intercept and (2) where the socioeconomic variables enter only as interaction terms with the air quality variables. For the quadratic, an *F*-test failed to reject the joint hypothesis of α_0 and α_s equal to zero (*F*-value of 1.0; 5 and 635 degrees of freedom). An *F*-test

also failed to reject the hypothesis of ρ_0 and ρ_s equal to zero in the semilog model (*F*-value of 0.53; 5 and 635 degrees of freedom).

Second, the inequality restrictions imposed by concavity are testable using the likelihood ratio method. This method compares a set of restricted estimates with the unrestricted estimates given in table 2. Examination of table 2, however, shows that the concavity restrictions are nonbinding. The diagonal elements of *B* and *D* are strictly negative and $|B|$ and $|D|$ are strictly positive. In this nonbinding case, restricted least squares estimates are identical to the unrestricted estimates (Judge et al. 1988). The results, therefore, fail to reject a concave bid function.¹²

¹² Diewert and Wales, and Geweke present alternative estimators for the general case where concavity restrictions may be binding.

Third, the significance of the substitution effect was examined. The coefficient of $GCAQ \times CAQ$ is negative and different from zero at any conventional level of significance in both the quadratic and semilog equations. These results confirm the predictions of theorem 1 and reject both independence and complementarity. Regional air quality conditions are substitutes in valuation.

Finally, a J-test (MacKinnon) was used to test the quadratic and semilog specifications. With the J-test, the quadratic and semilog specifications are tested against each other. To test the quadratic, the predicted values from the estimated semilog equation are entered as an additional explanatory variable in the quadratic equation and the equation is reestimated. If the coefficient on the predicted bid from the semilog equation is significantly different from zero, the predicted value contributes to the quadratic's explanatory power and the quadratic specification is rejected as incomplete. The predicted bid from the estimated quadratic equation is used to test the semilog in a similar manner.

J-tests were conducted for both the quadratic and the semilog. In the quadratic equation, the estimated coefficient for the predicted hc was 1.09 and had a t -value of 1.9 with 639 degrees of freedom. This result rejects the quadratic as a valid specification at the 90% significance level. In the semilog equation, the coefficient for the predicted hc was 0.0668 and had a t -value of 0.11 with 639 degrees of freedom. This result fails to reject the semilog specification at any conventional significance level. The semilog is therefore the better fitting specification for these data.

Concluding Comments

Environmental values are contextual—they are conditioned on the presence or absence of multidimensional resource flows. A conventional benefit cost design ignores the contextual nature of value data. Where resources are substitutes in valuation, a conventional benefit cost estimate exceeds the valid measure of net benefits. Where complementarity is present, a conventional benefit cost estimate understates the valid valuation. An accurate resource policy valuation requires a valid valuation design.

A valid valuation design has two characteristics. First, the aggregate valuation of a policy change is unique. For any given policy, there is only one valid valuation. Second, a theoretically

consistent disaggregated valuation can only be obtained by valuing policy impacts along a path of valuation. A valid path accounts for both the change in a specific policy component as well as the overall policy change.

The valid benefit cost design reduces to the conventional approach only if resource services are independent in valuation. Theorem 1 shows that such independence is unlikely. For a small number of impacts, substitution effects are expected for environmental services that are separated in consumption by space or uncertainty. Complementarity is possible if environmental services are tied together by a specific consumption activity.

The restrictions of a valid design apply to both contingent valuation and demand-based methods such as travel cost and hedonic analysis. Well-known procedures exist for estimating substitution and complementary effects in demand systems. Because the problem of interaction is new to the analysis of contingent valuation data, this paper has examined two different ways to implement a theoretically consistent contingent valuation. First, if the policy alternatives are predetermined, contingent valuation can be used to holistically evaluate benefits in a one-step, aggregate valuation.

Second, a sample of contingent value data may be used to estimate a multidimensional bid function. The estimation problem is similar to estimating a multiproduct cost function—the only requirements are a set of admissible functional forms and statistical design that elicits contingent values for a matrix of proposed environmental changes. The estimated bid function may be used to evaluate any combination of policy impacts within the range of a sample data set.

The econometric approach was empirically demonstrated using contingent valuation data for regional air quality. Quadratic and semilogarithmic bid functions were derived and estimated. Both functions conformed to the requirements of theory. Statistical specification tests indicated that the semilogarithmic function provided a better fit to the data used in the case study. Consistent with theoretical predictions, regional environmental conditions were shown to be strict substitutes in valuation.

These results should encourage further research to improve understanding of interaction effects in valuation. A range of alternative functional forms exist (Griffin, Montgomery, and Rister) that may be applied to the contingent valuation problem and tested for robustness and consistency with theory (Thompson).

In addition, the extent and strength of substitution should be examined in alternative valuation contexts. Intraregional packages of amenities offer cases of potential complementarity. These cases should be investigated to determine whether complementarity in activity production outweighs the substitution effects inherent in constrained valuation.

Tax Versus Quota Regulation: A Stochastic Model of the Fishery

Robert A. Androkovich and Kenneth R. Stollery

In a deterministic setting, it has been demonstrated that taxes and quotas can be equivalent regulatory instruments and that both can in principle induce an optimal allocation of resources in markets where externalities are problematic. In this paper we consider growth, harvest, and demand uncertainty within the context of Canada's Pacific halibut fishery and find that, while taxes remain the preferred instrument, the welfare losses arising from the use of individual boat quotas are minor.

Key words: externality, quota, regulation, taxation.

There is wide consensus on the need for regulation of industries such as fisheries where significant externalities exist and on the standard remedies to be applied. For example, in situations where the regulatory agency has full information and administration costs are equal, it is well known that per-boat quotas, taxes on the catch, and even per-boat effort controls are equivalent regulatory methods in theory. In practice, however, there is uncertainty about demand conditions, the size of the stock, and the productivity of the fleet; this situation not only creates great difficulty in actual resource management but prevents the alternative methods of regulation from being theoretically equivalent. In the work derived from Weitzman's general discussion of regulation under uncertainty, the ranking of taxes and quotas depends, for instance, upon the relative slopes of the marginal benefit and marginal social cost curves and whether the fish stock is observable without error (see Andersen, Anderson, Koenig 1984a).

This paper differs from the Weitzman approach with respect to the timing of decisions made by the regulatory authority and fishermen. Whereas in Weitzman's paper decisions are taken *ex post*, that is after the realization of the random variables, in the present model all economic agents take their decisions *ex ante*.¹ This approach is more realistic in that a boat owner

would typically have to decide whether to enter a particular fishery prior to knowing the price of fish, rather than after.² It turns out that this assumption guarantees that an appropriately set specific tax will be capable of inducing optimal behavior by the fishermen. This does not, of course, follow when decisions are made *ex post*.

Previous models introduce quotas that bind individual fishermen to produce a fixed amount. However, because fishing is inherently risky for participants as well as regulators, there is no guarantee that the quota will be met. Instead, this analysis follows Clark (1985b) by introducing per-boat quotas which truncate the distribution of catch, with catch above the quota returned to the ocean. As is well known, the mortality rate for returned fish is quite high. The importance of a potential divergence between the quantity of fish consumed and killed is obvious in that the future fish stock would be less than would be predicted on the basis of the growth equation and the quota.

In order to illustrate the extended quota model, the welfare effects of taxes and quotas are compared in the context of the Pacific halibut fishery, one with a homogenous fishing technology and fairly reliable sources of data. This comparison is done by simulating a stochastic dynamic program with parameters obtained from studies of this fishery. While taxes in the model are first-best in a limited-information sense, the

Robert A. Androkovich and Kenneth R. Stollery are, respectively, an assistant professor and a professor in the Department of Economics, University of Waterloo, Ontario.

The authors are indebted to three anonymous referees for their suggestions.

¹ Anderson makes a similar assumption.

² We are abstracting here from possible sharecontracting arrangements with processors. In many fisheries, processors absorb some of the risk by contracting for a minimum price on delivery. We are indebted to an anonymous referee for this observation.

welfare loss from individual quotas is relatively small.

The outline of the paper is as follows: the second section outlines the fishery model and compares the competitive, optimal, taxation, and quota equilibria. The sources of the parameters required for simulation of the model then are discussed, preparatory to the simulation of the model in the subsequent section. The final part offers conclusions.

The Fishery Model

The assumed fishery production function is a modified Schaefer type, given by

$$(1) \quad Q(t) = N(t)g[X(t), \theta(t)]e(t),$$

where $Q(t)$ is aggregate harvest during period t , $e(t)$ is effort per boat, $N(t)$ is number of (identical) boats fishing, $X(t)$ is stock size, $g[X(t), \theta(t)]$ is catch per unit effort (*CPUE*), and $\theta(t)$ is a random variable with mean unity which introduces output uncertainty.

The particular *CPUE* function is given by $g[X(t), \theta(t)] = \theta(t)/[\omega - \sigma X(t)]$, where ω and σ are parameters. The specific and somewhat unusual form of this function is required to make the subsequent analysis tractable. Quadratic benefit and per-boat cost functions are also required for a closed-form solution to the subsequent dynamic programming problem. Thus, an aggregate catch of $Q(t)$ has associated with it total benefits to consumers of

$$(2) \quad B[Q(t)] = [b_0 + \beta(t)]Q(t) - b_1 Q(t)^2/2,$$

and per-boat total costs of

$$(3) \quad C[e(t)] = c_0 + c_1 e(t) + c_2 e(t)^2/2;$$

with parameters $b_0, b_1, c_0 > 0$, one or more of c_1 and $c_2 > 0$, and $\beta(t)$ a random variable (with mean zero) which accounts for demand uncertainty.³ These functions imply a linear demand relationship for fish landings of the form $P = b_0 - b_1 Q$ (coinciding with that estimated by Cook for the halibut fishery) and a linear marginal cost curve for fishery effort. Given the paucity of data on effort costs, estimation of a nonlinear marginal cost function, even if theoretically justifiable, would not be possible with the available information. Following Koenig (1984a,b), we

also employ a linear growth relationship, approximating the growth of the fish stock by

$$(4) \quad X(t+1) = \phi_0 + \phi_1(X(t) - Q(t)) + \varepsilon(t);^4$$

where $\phi_0 \geq 0$, $\phi_1 > 0$, and $\varepsilon(t)$ is a random variable with mean zero.

The particular forms chosen for the benefit, cost, and growth relationships guarantee that the dynamic programming technique permits the conversion of the problem into one involving only current period variables. This, in turn, simplifies the comparison of the alternative regulatory regimes with the competitive case.

The regulatory authority's goal is the maximization of the present discounted value of the fishery's expected net benefits to society: equivalently, the sum of consumer surplus and economic rent. This is given by

$$(5) \quad V_0 = E_0 \sum_{t=0}^{\infty} \rho^t [B[Q(t)] - N(t)C[e(t)]];^5$$

where $0 < \rho < 1$ is the discount factor.⁵ Applying standard dynamic programming techniques,⁶ let

$$(6) \quad V_j[X(j)] = \text{Max}_{e(j)} E_j \sum_{t=j}^{\infty} \rho^t [B[Q(t)] - N(t)C[e(t)]].$$

Then,

$$(7) \quad V_t[X(t)] = \text{Max}_{[e(t), N(t)]} E_t [B[Q(t)] - N(t)C[e(t)] + \rho V_{t+1}[X(t+1)]],$$

and it is straightforward, though tedious, to show that the solution to this recursive relationship is given by

$$(8) \quad V_t[X(t)] = a_0(t) + a_1(t)X(t) + a_2(t)X(t)^2/2,$$

where the a_i also follow recursive relationships given by⁷

⁴ The long-lived nature of halibut makes it a multicohort fishery. If age-selectivity were allowed when setting catch quotas, the optimal quota could be determined by employing a Beverton-Holt population model in terms of numbers of fish, combined with a function such as Von Bertalanffy's describing the growth in weight of a single fish with age. This refinement was not considered in this paper because finding a closed-form solution to the dynamic program restricts the population growth function to a single linear form. A population model in terms of total biomass is equivalent to the disaggregated model in a steady-state, where the age distribution is constant.

⁵ $E_Z\{X\}$ is the expectation of $\{X\}$ at time Z .

⁶ See Chow, especially chapters 7 and 8.

⁷ In obtaining relationships (8)–(11), we assume an optimal policy is followed in all future time periods and that the three random variables are uncorrelated both inter- and intratemporally.

³ The demand uncertainty takes the form of a linear shift in the demand relationship.

$$(9) \quad a_0(t-1) = \rho[a_0(t) + a_1(t)\phi_0] + \rho a_2(t) \frac{[\phi_0^2 + \text{Var}(\varepsilon)]/2 + \chi^2/2\xi,}{\xi},$$

$$(10) \quad a_1(t-1) = \rho\phi_1[a_1(t) + a_2(t)\phi_0] + \chi[\sigma\Omega - \rho a_2(t)\phi_1^2]/\xi, \text{ and}$$

$$(11) \quad a_2(t-1) = \rho a_2(t)\phi_1^2 + [\sigma\Omega - \rho a_2(t)\phi_1^2]^2/\xi;$$

where $\Omega \equiv [c_1 + \sqrt{2c_0c_2}]$, $\xi \equiv E(\theta^2)[b_1 - \rho a_2(t)\phi_1^2]$, and $\chi \equiv [b_0 - \rho a_1(t)\phi_1 - \rho a_2(t)\phi_0\phi_1 - \omega\Omega]$.

It follows from (4), (5), and (8) that in the current period, the regulatory authority should choose both the number of boats and effort per boat so as to maximize the extended net benefit function⁸

$$(12) \quad ENSB = E\{B[Q] - NC[e] + \rho[a_0 + a_1[\phi_0 + \phi_1(X - Q) + \varepsilon] + a_2[\phi_0 + \phi_1(X - Q) + \varepsilon]^2/2]\}.$$

The first-order conditions for an interior maximum are given by

$$(13) \quad E\{[b_0 + \beta - b_1Q]g[X, \theta] - C'[e] - \rho\phi_1E\{[a_1 + a_2[\phi_0 + \phi_1(X - Q) + \varepsilon]]g[X, \theta]\} = 0, \text{ and}$$

$$(14) \quad E\{[b_0 + \beta - b_1Q]g[X, \theta]e\} - C[e] - \rho\phi_1E\{[a_1 + a_2[\phi_0 + \phi_1(X - Q) + \varepsilon]]g[X, \theta]e\} = 0.$$

The above characterization of the optimal harvest assumes the government has total control over the fishery. The equilibrium also represents a limited information optimum in that the government does not have knowledge of the realized values of the random variables when decisions are made. This situation represents a benchmark against which to compare more realistic cases in which the government either has no control over the fishery or controls it indirectly through the use of taxes or quotas.

A competitive situation can be modelled by setting $a_0 = a_1 = a_2 = 0$ and maximizing (12) with respect to e , with entry driving expected fishery rents to zero.⁹ This yields

$$(15) \quad E\{[b_0 + \beta - b_1Q]g[X, \theta]\} = C'[e] \text{ and}$$

$$(16) \quad E\{[b_0 + \beta - b_1Q]g[X, \theta]e\} = C[e]$$

as the equilibrium conditions. Although yielding the optimum level of per-boat effort, the usual stock externality represented by the absence of the a_i terms means a competitive fishery will generally lead to overutilization of the stock. An issue of primary concern is the extent to which either a specific tax or quota will mitigate the externality problem in a stochastic setting.¹⁰

With a specific tax (τ), effort will be expended and entry will occur until

$$(17) \quad E\{[b_0 + \beta - b_1Q - \tau]g[X, \theta]\} = C'[e], \text{ and}$$

$$(18) \quad E\{[b_0 + \beta - b_1Q - \tau]g[X, \theta]e\} = C[e].$$

Acting as a principal with the fishermen as agents, the government will then

$$(19) \quad \text{Max}_{[\tau]} E\{B[Q] - NC[e] + \rho[a_0 + a_1[\phi_0 + \phi_1(X - Q) + \varepsilon] + a_2[\phi_0 + \phi_1(X - Q) + \varepsilon]^2/2]\}$$

subject to (17) and (18); in the process all fishery rents becoming tax revenues.¹¹ The resulting first-order condition can be written in the form

$$(20) \quad E\{[b_0 + \beta - b_1Q]g[X, \theta]e\} - C[e] - \rho\phi_1E\{[a_1 + a_2[\phi_0 + \phi_1(X - Q) + \varepsilon]]g[X, \theta]e\} = 0.$$

It follows immediately, from the identity of equations (14) and (20), that if the regulatory authority chooses a specific tax which satisfies $\tau = \rho\phi_1E\{[a_1 + a_2[\phi_0 + \phi_1(X - Q)]]\}$, the number of boats in the fishery, the effort per boat, and the level of expected net social benefits will be identical to their values in the limited-information optimal situation. Thus, a specific tax can, in principle, induce a competitive fishery to harvest optimally in a stochastic as well as a deterministic environment.

It is of interest to compare the optimality of taxation in our model with the conclusions derived by Koenig (1984a,b 1985), who finds tax-

⁸ Because the problem has been converted into one involving only current period variables, time references are dropped in the formulas which follow. a_0 , a_1 , and a_2 represent shadow prices in (12), in that they account for the effects of current variables on future net benefits.

⁹ This formulation assumes fishery firms are risk-neutral. The justification for this assumption derives from the finding by Andersen that risk aversion by fishermen under stock or price uncertainty reduces both effort and expected catch, possibly even to sub-optimal levels. Because overfishing motivates regulatory intervention in the first place, by assumption the degree of risk aversion on the part of fishing firms must be comparatively low.

¹⁰ In a deterministic environment a specific tax can, in principle, eliminate the externality problem if the tax is set equal to the shadow value of the stock.

¹¹ The costs associated with administering differing regulatory methods are not considered. Different costs of administering taxes and quotas would affect the losses in expected net social benefits associated with their respective usage. For instance, if a quota regime were less costly to manage than a tax regime, then the results summarized in table 1 might be reversed, with a quota dominant.

ation a suboptimal instrument. The difference arises from the divergent treatments of uncertainty in our paper and Koenig's. He assumes that while output decisions are made with full information—after the realization of the random variables—the rates of taxation are set *ex ante*. This asymmetry of information, in turn, guarantees that taxes are suboptimal in a full-information sense.¹² We assume instead that decisions are made by both the regulatory authority and the boat owners prior to the realization of the random variables; that is, the size of the fleet will be nonrandom *ex ante*, and the decisions regarding the rate of taxation and whether to fish must both be made with incomplete information. This symmetry of information within our model guarantees that a specific tax will be first-best given the limited information.

erwise, the future stock will be less than would be predicted from the growth equation and the quota, and the fishery's expected net benefits to society would be inaccurate if this issue were to be ignored. To illustrate, define m as the mortality rate for returned fish, and

$$S = \begin{cases} 1 & \text{if } \theta \leq \theta^* \\ 0 & \text{if } \theta > \theta^* \end{cases}.$$

Then, actual (per-boat) mortality is

$$\bar{q} = Sg[X, \theta]e + (1 - S)\{q + m(g[X, \theta]e - q)\}.$$

It follows that if individual boat quotas are used, the level of the fisheries expected net benefits to society is given by

$$(21) \quad ENSB[q, N, e] = E \left[\int_0^{\theta^*} B[Q]f(\theta)d\theta + \int_{\theta^*}^{\infty} B[Nq]f(\theta)d\theta - NC[e] + \rho \int_0^{\infty} \left[a_0 + a_1[\phi_0 + \phi_1(X - N\bar{q}) + \varepsilon] + a_2[\phi_0 + \phi_1(X - N\bar{q}) + \varepsilon]^2/2 \right] f(\theta)d\theta \right];$$

The manner in which we model risk also implies that when individual boat quotas are used as the method of regulation, they change the harvest function by truncating the catch distribution. The harvest function becomes

$$Q = \begin{cases} Ng[X, \theta]e & \text{if } \theta \leq \theta^* \\ Nq & \text{if } \theta > \theta^* \end{cases};$$

where q is the per boat quota, and $\theta^* = [\omega - \sigma X]q/e$ is the value of θ associated with a catch of q , stock level X , and per-boat effort e .

Of course, the possibility of a catch in excess of the quota now arises. We assume that any such excess is immediately returned to the ocean. It is known that the mortality rate for returned fish is quite high; thus in modeling a quota under this type of uncertainty it is important to account for a potential divergence between the quantities of fish consumed and killed.¹³ Oth-

where $f(\theta)$ is the probability density function for the random variable θ , and the expectations operator refers to the random variables β and ε . Acting once again as a principal, the regulatory authority will then

$$(22) \quad \max_{[q, N, \hat{e}]} ENSB[q, N, \hat{e}] \text{ subject to}$$

$$\hat{e} = \operatorname{argmax}_{[e]} \int_0^{\infty} [b_0 - b_1 Q]g[X, \theta]ef(\theta)d\theta - C[e].$$

The constraint, equation (22), implies that each boat owner applies effort to the point where his expected marginal value equals his marginal cost.¹⁴ The regulatory authority, being aware of the boat owner's decision-making processes, accounts for this in setting the quota and the fleet size.¹⁵

¹² Within the context of the model specified, this situation would involve boats entering or leaving the fishery depending upon the realized values of the random variables.

¹³ Myhre estimates the mortality of released halibut at 32%; this figure was used in the simulation analysis to follow. Results were not highly sensitive to the value of this parameter.

¹⁴ In characterizing \hat{e} , the boat owners are assumed to take the price and their individual quotas as given.

¹⁵ A situation in which an industry-wide quota is established, in conjunction with control over the size of the fleet, is formally equivalent to the one which we have modeled since the boats in the fleet are homogenous both in their use of inputs and in the mortality of fish returned to the sea. The approach we follow in solving the quota problem is analogous to that which would be followed in (numerically) solving a boundary value problem.

Sources of Model Parameters

In order to gain insight into the welfare costs associated with the implementation of quotas, a specific fishery is considered. Parameters are required for the demand and cost of effort functions and the fishery biological relationship. The Pacific halibut fishery was chosen to illustrate the model solution because it has a relatively simple (longline) fishing technology, as well as a long regulatory history giving rise to reliable data. For these reasons this industry has been quite extensively studied, and parameter estimates from this previous research are employed.

Cook estimated a linear (inverse) demand relationship for regulatory area 2 (mainly the Canadian sector). With the catch measured in tons, the price in 1961 dollars, and standard errors in parentheses, the estimated function was

$$P = 720.0 + 2220.0P_s - 1.02SL - 0.04Q$$

$$(171.4) \quad (325.4) \quad (0.54) \quad (0.0098)$$

$$\bar{R}^2 = 0.77, D-W = 1.62,$$

Method: ordinary least squares

where P_s is the price of salmon (a major substitute) and SL is the length of the fishing season (affecting the catch quality).¹⁶ For the simulation, this equation was collapsed by substituting their average 1968–80 values, giving

$$P = 1200.0 - 0.04Q$$

$$(603.3) \quad (0.0098)$$

Because this represents the marginal social benefit from harvesting area 2, the estimates of b_0 and b_1 are 1200.0 and 0.04, respectively, with the variance of β derived from the b_0 coefficient's standard error, becoming $\text{var}(\beta) = 1.75 \times 10^4$.

The parameters for the per-boat cost of effort function were established using Catch Summary Reports from 1975–80 on the Canadian Pacific halibut fleet made available by the Canadian Department of Fisheries and Oceans (Stollery).

Halibut vessels were defined as those taking 80% or more halibut. The reports showed the fleet to be relatively homogenous, for of ninety-seven boats in 1979, eight-three were between 30 feet and 60 feet in length, and these represented 89% of the total catch. They also showed an average capital value of \$491,293 per boat in 1961 dollars. Employing a real discount rate of 5%, 4.4% capital depreciation, and insurance costs of 3.8% of vessel value, yearly fixed costs per boat are estimated at 13.2% of capital value, or $c_0 = \$64,895.00$. The values for depreciation and insurance were not available in the Catch Summary Reports, but were taken from "Basic Economic Indicators, Halibut," a 1968 survey of the U.S. Pacific Halibut fleet by the U.S. Bureau of Commercial Fisheries, Department of the Interior, 1970. Prior to 1979–80, when a limited-entry licensing scheme was first imposed, regulation in the halibut fishery consisted only of controls on season length (Cook and Copes). Thus, the period before 1980 represents open-access, and the model is calibrated to a competitive benchmark. Cook and Copes' data imply an average effort per boat of 1357.5 skate-soaks over the 1968–80 period.¹⁷ Equating the marginal and average costs of effort at this value gives $c_1 = -\$55.55$ and $c_2 = \$0.07$ for the remaining cost function parameters.

The catch per unit effort ($CPUE$) function is specified in the model as $g[X, \theta] = \theta/[\omega - \sigma X]$.¹⁸ The parameters ω and σ are obtained by taking a first-order Taylor-series approximation of expected industry $CPUE$, defined as $\bar{g}[X] = E\{g[X, \theta]\} = [\omega - \sigma X]^{-1}$, at \bar{X} (the mean stock level), then constraining this approximation to the traditional Schaefer function $g_0 X$ at \bar{X} . Equating $\bar{g}[X] = \bar{g}[\bar{X}] + \sigma \bar{g}[\bar{X}]^2 (X - \bar{X})$ with $g_0 X$ implies $\sigma = (\bar{X} \bar{g}[\bar{X}])^{-1} = \omega/2\bar{X}$ and $4\sigma/\omega^2 = g_0$. Employing data prior to limited-entry licensing in 1980, Cook calculated the mean stock level implied by combining the Schaefer production function and the Verhulst (logistic) population growth equation at bioeconomic equilibrium, giving $\bar{X} = 29,334$ tons. This gives $\bar{g}[\bar{X}] = 0.04328$ tons per skate-soak and $g_0 = 0.12 \times 10^{-5}$, implying $\sigma = 7.875 \times 10^{-4}$ and $\omega = 46.216$ for the $CPUE$ parameters.

Because the dispersion of the catch each year

¹⁶ The salmon price was exogenous from the standpoint of the regulators, but they were in fact controlling the season length during the period prior to the imposition of limited-entry licensing in the 1980s. We have not modeled season controls explicitly as a regulatory tool; but, from the standpoint of controlling fishery effort, an indirect benefit of such control in our model would be a reduced variance associated with the estimation of social benefits. Season length controls may also mean that SL and Q were correlated over the estimation period, possibly introducing multicollinearity. As long as the equation errors are independently distributed this will not bias the coefficients, but the coefficient standard errors (and thus the estimate of β 's variance) could have been affected by this statistical problem.

¹⁷ In the halibut fishery effort is measured in "skate-soaks" per time period. A skate is a (standard) length of fishing line which is left in the water (soaked) for a set amount of time.

¹⁸ This particular form for the $g[X, \theta]$ function was required to make the model tractable. It is an approximation to $g[X, \theta] = g_0 \theta X$, i.e., the traditional Schaefer harvest function.

around its mean value is not known, no information on the variance of θ is available from this method. In 1979, the year prior to the imposition of limited-entry licensing, ninety-seven boats were in the fishery. In order to calibrate the competitive equilibrium to this benchmark, appropriate values must be specified for any parameters lacking empirical verification. Only the variance of θ falls into this category. Thus, the specification of $\text{Var}(\theta) = 0.225$ ensures that the competitive equilibrium is realistic.¹⁹

The parameters ϕ_0 and ϕ_1 characterize the yearly growth of the fish stock [equation (4)]. This linear approximation to the traditional Verhulst logistic growth function is also necessary in order to solve the stochastic dynamic programming problem. Because stock size is not directly observable, (4) cannot be estimated directly; the only available proxy is industry-wide CPUE or $g[X]$.²⁰ For purposes of estimation, we assume $g[X] = g_0X$, which in conjunction with (4) yields

$$CPUE_t = \phi_0 g_0 + \phi_1 [CPUE_{t-1} - g_0 Q_{t-1}] + g_0 \epsilon.$$

This, of course, could be estimated using nonlinear least squares to obtain ϕ_0 , ϕ_1 , and g_0 . However, Cook estimated the traditional logistic growth function for the stock, providing information on g_0 .²¹ Therefore, g_0 is constrained to the estimate of 0.12×10^{-5} , obtaining $\phi_0 = 6259.63$ and $\phi_1 = 0.87216$. The variance of ϵ was determined as the regression error variance divided by g_0^2 , becoming $\text{Var}(\epsilon) = (7921.84)^2$.

Given the parameter values above, the coefficients a_0 , a_1 , and a_2 characterize the optimal $V(X)$ function, i.e., the expected value of the

fishery's net benefits to society. As was pointed out previously, these coefficients follow recursive relationships: functions $f_0[\cdot]$, $f_1[\cdot]$, and $f_2[\cdot]$ exist such that

$$a_0(t-1) = f_0[a_0(t), a_1(t), a_2(t); \text{parameters}],$$

$$a_1(t-1) = f_1[\dots], \text{ and}$$

$$a_2(t-1) = f_2[\dots].$$

The CHOW-YORKE fixed-point algorithm from the ACM algorithms distribution service (see Watson, Watson and Fenner) was used to determine their convergent values; $a_0^* = 10006026.8283$, $a_1^* = -505.4409$, and $a_2^* = 0.0247$. These values were substituted into the various first-order conditions, allowing us to determine, for the alternative cases, the optimal number of boats, effort, and the maximum expected net social benefits. Where required, the BRENTM subroutine (also available from ACM) was used to solve the systems of nonlinear equations, and all integration was completed using the subroutine RKF45 (Forsythe, Malcolm, and Moler).

Simulation Results

Recall that in a first-best situation, the government has complete control of the fishery and chooses the level of effort per boat and the number of boats so as to maximize the fishery's expected net benefits to society. Solving the dynamic program with the parameter estimates, effort is 1,357.5 skate-soaks per year, approximately seventy-one boats are in the fishery, and expected output is 4,155.3 tons with expected net social benefits of \$5,819,967.34, as shown in the first column of table 1.

In comparing the optimal fishery with the competitive case, the fleet under competition is larger (by an estimated 37%) and the expected net social benefits of the fishery are correspondingly reduced. The effort levels in the first-best and competitive cases are equal because the form that has been adopted for the CPUE function ensures that, in both cases, effort is applied to the point of minimum average cost of effort. Expected net benefits are positive even in the competitive case because the price will equal marginal benefits and will be exceeded by average benefits.

We have indicated how a specific tax can induce optimal behavior in this model. With the parameters the optimal tax (τ) is \$74.35 per ton,

¹⁹ For the simulation experiment, we assume θ is distributed according to a gamma density function, i.e.,

$$f(\theta) = \lambda^\tau \theta^{\tau-1} e^{-\lambda\theta} / \Gamma(\tau), E[\theta] = \tau/\lambda, \text{ and } \text{Var}[\theta] = \tau/\lambda^2;$$

where $\Gamma(\tau) = \int_0^\infty x^{\tau-1} e^{-x} dx$ and $r = \lambda = 4.89$.

²⁰ CPUE is a nonlinear function of X according to the yield function, but we regard this as a necessary approximation. If $g[X]$ were a correct representation of the yield-stock relationship in the fishery, the stock growth function parameters could be estimated by inverting $g[X]$ in order to obtain effort per unit catch (EPUC) as a linear function of $EPUC_{t-1}$ and Q_{t-1} .

²¹ The logistic growth function is given by

$$\Delta X(t)/X(t-1) = v(1 - X(t-1)/K) + \epsilon(t);$$

where v and K are parameters. Subtracting the Schaefer production function gives a net change in CPUE of

$$CPUE(t)/CPUE(t-1) = (1 + v) - vCPUE(t-1)/K g_0 - g_0 E(t-1) + \epsilon(t);$$

where $E(\cdot)$ is aggregate effort. Ordinary least squares estimation then yields the estimate of g_0 .

Table 1. A Comparison of the Alternative Regimes

	First-Best	Comp.	Specific Tax	Quota
Effort	1,357.5	1,357.5	1,357.5	1,397.8
Fleet size	70.7	97.0	70.7	71.7
Tax rate			74.4	
Quota				482.5
Expected output	4,155.3	5,698.3	4,155.3	4,338.5
ENSB	5,819,967.3	5,787,239.2	5,819,967.3	5,815,285.5
CS	415,922.2	782,159.5	415,922.2	453,394.2
RENT	308,953.3	0	308,953.3	280,196.0
DEFNB	5,095,091.8	5,005,079.7	5,095,091.8	5,081,695.2

Note: *ENSB* corresponds to the presented discounted value of the fishery's expected net benefits to society in the various situations. *CS* measures the consumer surplus, and *RENT* the economic rent accruing during the initial period of the planning horizon. Finally, *DEFNB* refers to the present discounted value of the expected future net benefits to society, i.e.,

$$DEFNB = \rho V_{t+1}[X(t+1)],$$

so,

$$ENSB = CS + RENT + DEFNB.$$

or approximately 7.2% of the industry price. Interestingly, this magnitude is similar to the tax proposed by Pearce for the British Columbia salmon fishery. Given the unpopularity of the Pearce tax on salmon, it is likely that a 7.2% halibut tax would meet the same fate.

Of greater interest are the individual boats quotas. We estimate an optimal quota of 482.5 tons per boat, with per boat effort (1,397.8 skate-soaks) and the size of the fleet (71.7 boats) being marginally larger than first-best levels. The quota succeeds in removing 85.7% of the loss of expected net social benefits associated with competitive behavior in this fishery.²² The truncating nature of the quota implies that its imposition will lead to a reduction in effort per boat, *ceteris paribus*. Recognizing this, the regulatory authority will reduce the size of the fleet below the competitive level in order to increase the expected marginal value of effort, thereby inducing a secondary increase in effort. As the fishery moves from a competitive to a quota equilibrium, the increase in predicted effort is consequence of this secondary adjustment.²³

Given these results, the actual situation in the fishery is of obvious interest. While season controls were in effect prior to 1979–80, since then there has been limited-entry licensing. The fun-

damental weakness of this scheme is well known: it does not control the fishing capacity of the fleet. Pearce recognizes this problem and recommends that individual boat quotas be adopted. "The outstanding advantage of this approach is that it eliminates the basic cause of overcapacity in the fishing industry by removing the incentives of individual fishermen to protect and increase their share of the catch" (Pearce, p. 84). He also suggests that quota licenses be issued for a limited period. When that period has elapsed, the government would then hold an auction and sell the quota license to the highest bidder. In this way, the government would recoup the rent associated with the quota.

The small difference between taxes and quotas in these simulations is surprising, and we are led to question whether the structure of the model has forced this result. For instance, the assumption that β , θ , and ϵ are uncorrelated is quite strong: it is possible to envisage situations in which this would not follow. The inclusion of either inter- or intratemporal correlation, or both, is found to affect the differences in expected net social benefits when comparing the competitive, tax, and quota regimes.²⁴ For instance, increasing the intratemporal correlation coefficient between ϵ and θ from zero induces additional losses in expected net social benefits for both the competitive and quota cases. To be more specific,

²² Because the rents associated with the quota accrue to the fishermen, we would almost certainly have observed a decrease in the optimal season length if the model had been formulated to consider this issue.

²³ The second-best nature of the quota will, in general, prevent effort per boat from being at an optimal level.

²⁴ While it is feasible to adjust the analyses of the first-best, tax, and competitive cases to allow for nonzero correlation coefficients, we are only able to approximate their impact with quotas.

if ε and θ are perfectly correlated the loss in expected net social benefits arising from competitive behavior will increase to \$53,929.23 and a quota would then remove 85.2% of the loss. Of course, the possibility of intertemporal correlation also exists. Suppose that, in addition to the intratemporal correlation between ε and θ discussed above, ε follows a first-order autoregressive process, i.e., $\varepsilon(t) = \gamma\varepsilon(t-1) + \mu(t)$, where γ is set equal to 0.50, and $\mu(t)$ is a random variable. Then the loss is expected net social benefits arising from competitive behavior falls to \$46,277.67, and a quota removes 86.6% of the loss. Thus, the lack of both inter- and intratemporal correlation may have introduced bias into the results summarized in table 1, but the direction of this bias is unclear.

The particular forms chosen for the demand, cost, and growth functions also may have constrained the result. For instance, suppose that costs are a cubic rather than a quadratic function of effort. Sensitivity analysis reveals that, if marginal costs are an increasing (concave/convex) function of effort, then the losses associated with competitive behavior and the quota regime are (increased/decreased). The potential bias arising from the particular demand relationship which is adopted is equally unclear. Suppose, for instance, that b_0 and b_1 are adjusted so as to keep the price constant at a particular output level: the price elasticity of demand will then change, and we find that the losses associated with free entry and the quota are inversely related to the elasticity. An analogous exercise with respect to the growth function's parameters yields similar results. The original specification of the various functional relationships may thus have introduced bias into the analysis, but in an unknown manner.

Concluding Comments

This paper has contributed to the continuing research on regulatory methods for commercial fisheries under uncertainty. While the timing of decision-making guarantees that taxation will be first-best in a limited information sense in our model, the loss of expected net benefits associated with a quota are small. This finding is especially surprising because catch and kill are typically not identical in the presence of a quota as a result of the high mortality rate of fish returned to the ocean. Given the political difficulty that regulators face in imposing taxes on

catch, a properly designed quota may be the best practical alternative for fishery regulation.

Endangered Species and the Safe Minimum Standard

Richard C. Ready and Richard C. Bishop

The safe minimum standard of conservation is a decision rule for problems like endangered species preservation that involve irreversibility and uncertainty. It has been motivated as the minimax-loss solution to a two-person game against nature. However, two equally plausible games can be used to model decisions involving endangered species. For one game, the safe minimum standard, and therefore preservation, is preferred. For the other game, extinction is preferred. Although the safe minimum standard is intuitively appealing, it cannot be motivated by game theory.

Key words: conservation, endangered species, irreversibility, uncertainty.

Extinction of plants and animals is an example of a class of economic problems that involve irreversible destruction of environmental amenities and uncertainty over the future value of those amenities. If preserved, a species might become an important resource in the future. However, how valuable a particular species might become is at present unknown. At the same time, preservation of species may involve near-term costs. Ideally, economic analysis of issues involving endangered species would focus on the potential Pareto improvement criterion using cost-benefit analysis, including consideration of quasi-option value (Arrow and Fisher, Fisher and Hanemann). This approach may be stymied, however, by inability to assign probabilities to alternative outcomes or even to place bounds on potential payoffs from preservation (Smith and Krutilla, Bishop 1979).

Ciriacy-Wantrup proposed an alternative decision rule for problems involving irreversibility and pure uncertainty, the safe minimum standard of conservation (*SMS*). Wantrup was concerned with "flow resources with a critical zone," renewable resources where irreversible depletion is possible. Wantrup's concern was that the

irreversible loss of potential resources would limit society's ability to adapt to a changing world, leading to stagnation and the risk of "immoderate future losses." He argued that the appropriate policy for critical zone flow resources was to insure against such losses by adopting the safe minimum standard of conservation, which states that flows should be maintained at a level that makes it feasible to rebuild the stock in the future. For example, Ciriacy-Wantrup and Phillips stated that:

The objectives of conservation policy—and of many other public policies—can often be compared with the objectives of an insurance policy against serious losses that resist quantitative measurement. Here the objective is not to maximize a definite quantitative net gain but to choose premium payments and losses in such a way that maximum possible losses are minimized. (Ciriacy-Wantrup and Phillips, p. 28)

Wantrup personally applied the *SMS* concept to water quality (Ciriacy-Wantrup 1961) and agricultural land (Ciriacy-Wantrup 1964) as well as endangered species (Ciriacy-Wantrup 1952, Ciriacy-Wantrup and Phillips).

Whereas cost-benefit analysis has a sound theoretical foundation in the potential Pareto improvement criterion, the safe minimum standard has not been adequately tied to a theoretical model of social choice. Wantrup claimed that the safe minimum standard could be "regarded as a conceptual relative of the min-max solution or saddle point of a two-person strictly determined game" (Ciriacy-Wantrup 1968, p. 89), but he never formalized this relationship. Bishop (1978) attempted to formalize the relationship between

the SMS and the minimax solution to a two-person game, but he incorrectly specified the loss matrix for the game he envisioned.¹

The purpose of this paper is to explore the link between game theory and the safe minimum standard of conservation. This will be done in the context of species preservation, but the results are applicable for a wide range of decisions involving irreversible destruction of natural resources. We identify two separate games that could be used to model endangered species preservation decisions, the insurance game and the lottery game. While either model is plausible, they yield completely different conclusions regarding endangered species policy.

The Insurance Game

A highly simplified version of the problem helps focus attention on central issues. Suppose that society is confronted with whether or not to develop resources where development will entail the extinction of a species. The development benefits will be symbolized by B_d , where B_d is assumed net of any known losses in use or non-use values associated with the extinct species.² Nevertheless, $B_d > 0$ is assumed to hold. Otherwise, extinction would never be efficient. Also, it will be assumed that preservation of the species requires only that development be abandoned; there are no out-of-pocket costs for preservation.

Following Wantrup, extinction is assumed to entail the possibility of future losses, symbolized by L , which are assumed to be large; L is at least large enough so that $L > B_d$. For example, L might be the losses incurred from the possible, but uncertain, outbreak of some deadly disease like AIDS. If the species in question is present, a cure for the disease will be found with certainty, making losses zero. However, if the species is extinct, the disease will, if it does occur, inflict heavy losses on society, measured by L . Uncertainty is modeled by two policy-independent future states of the world, state 1 and state 2, corresponding to an outbreak of the disease and no outbreak, respectively. We assume

that L and B_d are known, but that the probabilities of state 1 and state 2 are unknown.

In game-theoretic terms, society has two possible strategies, *SMS* and *DEV*, representing the maintenance of the safe minimum standard and development, respectively. The baseline for measurement of losses is arbitrarily chosen as a situation of no disease and no development. The loss matrix for the insurance game is constructed by measuring gains and losses from that baseline and is presented in table 1. Each row depicts a social strategy, and each column represents a state of the world. In the upper left-hand corner, the *SMS* is chosen and an outbreak of the disease occurs. Because the species is present, the disease is cured and no losses are sustained. Thus, the loss, relative to the baseline, is zero. If the *SMS* were chosen and the disease did not occur (the upper right-hand corner), the loss would again be zero. Choosing development implies a gain of B_d (a loss of $-B_d$). If development is chosen and an outbreak of the disease does not occur, then the total loss is simply $-B_d$. If development is chosen and the outbreak does occur, then the total loss is $L - B_d$, which is positive by definition. This is the immoderate future loss that Wantrup wanted to avoid. If this situation is viewed as a two-person, zero-sum game played against nature, the strategy that minimizes that maximum possible loss is preferred. Under the *SMS*, the maximum possible loss is 0. Under *DEV*, the maximum possible loss is $L - B_d$. The preferred strategy is then *SMS*.

Wantrup's idea of insurance against large future losses is implemented in that choosing the *SMS* insures that such losses will be avoided. Unfortunately, the conclusion that the *SMS* is the recommended policy for endangered species decisions is not robust to the specification of the game. To illustrate this, a different game, called the lottery game, is presented.

The Lottery Game

The assumptions are changed only slightly. Suppose that the same endangered species and the same disease are involved. In the insurance game, we assumed that the endangered species held the key for curing the disease, and that the outbreak of the disease was uncertain. In the lottery game, the disease is assumed to occur with certainty, but there is uncertainty about whether preservation of the species will lead to a cure. In state 1, the species does hold the cure, in state 2, it does not. An example is a disease such as

¹ In his loss matrix, Bishop (1978) double counted the benefits from species preservation in his state 2.

² Following Krutilla, non-use values are values that are held by individuals above and beyond values associated with personal use of the species. To the extent that such values are motivated by benevolence toward future generations (Krutilla's "bequest values"), they may incorporate consideration of the avoidance of the loss L , leading to some double counting in our game matrix. This issue will be ignored here in order to concentrate on the nature of the game.

Table 1. Loss Matrix for the Insurance Game

Strategy	State		Max Loss
	1	2	
<i>SMS</i>	0	0	0
<i>DEV</i>	$L - B_d$	$-B_d$	$L - B_d$

cancer, that we know will occur. The endangered species could be a plant that might provide chemical compounds helpful in treating cancer.

The baseline for the lottery game is no development and no cure. The loss matrix for the lottery game is presented in table 2. If the *SMS* is chosen and state 1 occurs, the losses from the disease are avoided, giving net losses to society, relative to the baseline, of $-L$ (a gain). If the *SMS* is chosen and state 2 occurs, the baseline situation occurs with net losses of 0. If *DEV* is chosen, the disease will not be cured regardless of the state because the species is unavailable. Net losses are $-B_d$ (a gain) in either state.

The lottery game captures an often-heard argument for species preservation: that endangered species should be saved because they may lead to the discovery of important new resources. Preserving the species is analogous to buying a lottery ticket. Adopt the *SMS* and society may (or may not) win big.

The maximum possible loss under the *SMS* in the lottery game is 0, while under *DEV* it is $-B_d$, which is less than zero. The minimax strategy for the lottery game therefore is to choose development, and guarantee a gain of B_d , even though it means extinction of the species and thus insures that society will suffer the losses associated with the disease. Thus, a seemingly innocuous modification of the motivation of the problem has completely reversed the conclusion.³

Table 2. Loss Matrix for the Lottery Game

Strategy	State		Max Loss
	1	2	
<i>SMS</i>	$-L$	0	0
<i>DEV</i>	$-B_d$	$-B_d$	$-B_d$

³ A similar reversal of the conclusion would occur in the insurance game if a third state of the world were introduced, where an outbreak of the disease occurs but the species does not provide the cure.

Taking Stock

Neither game captures the nature of the problem better than the other. Wantrup clearly viewed species preservation according to the insurance game. Bishop tended to motivate the problem along the lines of the lottery game but incorrectly specified the loss matrix, leading him to conclude the *SMS* was the preferred strategy. While Fisher and Hanemann operated in a cost-benefit framework, they discussed aspects of both games, and focused attention on a problem that is best modeled by the lottery game. Here, we have shown that, depending on how the endangered species problem is motivated, the conclusions reached using a minimax loss decision rule could be completely reversed. Use of a game-theoretic framework gives structure to the problem. However, *SMS* cannot be motivated as the minimax-loss solution to a two-person game against nature.

Interestingly, using the minimax-regret decision rule, the conclusion is that the *SMS* should be adopted for either the lottery game or the insurance game. There is some evidence that individuals consider regret when making decisions under uncertainty, rather than maximizing expected utility (Loomes and Sugden). Perhaps the intuitive belief that endangered species should be preserved is motivated by regret considerations. However, while individuals may make decisions based on regret, it is questionable whether public decisions regarding endangered species should be made that way.

Rejection of game theory does not necessarily imply rejection of the *SMS* as a decision-making policy, although it does leave us without a theoretical foundation for that policy. Society may choose to adopt the *SMS* not because it results from a rigorous model of social choice, but simply because individuals in the society feel that the *SMS* is "the right thing to do." Indeed, the Endangered Species Act of 1966 (with subsequent amendments) seems to codify that feeling, allowing only a limited role for economic analysis in endangered species decision making.

Demands for Local Public Sector Outputs in Rural and Urban Municipalities

Melville L. McMillan and Joe Amoako-Tuffour

Little is known about local public services demands in rural municipalities and how they differ from demands in urban municipalities. Local public sector output demands in rural and urban municipalities in Victoria, Australia, are studied here using a system of equations approach based on the translog model. Expenditure, price, and substitution elasticities are reported. Demands differ between rural and urban municipalities and even among the (especially urban) subclasses.

Key words: Australia, local government, municipal service demands, rural, urban.

Many studies have considered the demands for municipal government outputs, but these studies have focused almost exclusively on urban municipalities (e.g., Bergstrom and Goodman; Deacon; Ladd; Hayes 1985, 1986; Hayes and Grosskopf; Hayes and Slottje; McMillan, Wilson, and Arthur; Perkins). With rare exceptions (Kiefer, McMillan 1985), rural municipalities have been ignored. Indeed, it is unusual that differences between types of municipalities are central to any such analysis (Hayes 1985; McMillan, Wilson, and Arthur). The objective of this paper is to compare the demands for local public services in rural jurisdictions with those in urban municipalities. The data encompass all municipalities in the State of Victoria, Australia. Municipalities there range from densely populated cities in the Melbourne metropolitan area to sparsely populated rural municipalities.

Demands for local public services may differ between rural and urban municipalities for various reasons. The spatially dispersed nature of rural households and business is expected to make

road transportation a priority in order to service rural enterprises, market their products, and provide access to services available only in urban centers. A sparse population also reduces the potential economies of public services like water, sewerage, and garbage and results in more private provision. The higher travel costs incurred to use centrally located public recreational and cultural facilities may reduce the demand for them. The importance of property ownership in rural municipalities and local governments' reliance on property taxes may imply a perceived greater property tax burden in rural communities and a more conservative attitude toward local government spending. Also, the relative numbers and the political weight of households in rural and urban portions of non-homogenous municipalities may influence demand. The data studied here indicate distinctly different expenditure patterns between rural and urban local governments. The objectives are to determine whether such differences warrant disaggregation of municipalities by type when examining local public service demands and, if so, what differences in demand exist.

The characteristics of the demands for six municipal services are reported for rural and urban municipalities. While attention is focused on these two groups, the rural group is actually the combination of two types of rural municipalities (rural shires and rural with small urban centers) and the urban group is a composite of three types of urban municipalities (small independent urban, suburban, and central metro-

politan cities). Thus, we also provide the results for each subgroup and briefly consider within rural and within urban subgroup differences.¹ The nature of preferences for municipal services based on all 211 Victoria municipalities together is reported in McMillan and Amoako-Tuffour (1988b).

In the following section, the characteristics of the municipal classes are discussed. The indirect translog model used to estimate the demand functions then is outlined and the data are discussed. Next, the empirical results and the estimated elasticities are reported by municipality type. A conclusion completes the paper.

Municipality Classification and Characteristics

The mean values of the local characteristics for the various classes are reported in table 1. When considering the two group rural-urban division, in general, the rural municipalities have much smaller populations, lower per capita incomes, a larger tax base per capita but a smaller portion being residential property, greater local expenditures per capita (notably for roads), and a less dense and less urbanized population than the urban municipalities. Comparing the two rural categories, the rural shires have smaller populations and less (indeed almost no) population growth, a smaller share of their population is in urban areas (10% as opposed to 37%), and, although both types of rural municipalities typically incorporate several population centers, the average population of each center is 65 in the rural shires in contrast to 330 in the other group.

Three subgroups constitute the urban municipalities. One group is essentially the cities in the central portion of the Melbourne area plus two nearby cities; it is designated as the central metropolitan cities group. These cities are large, densely populated, house a somewhat older population, and are experiencing population decline. Provincial cities dominate the small, independent urban center group. The municipalities in this group are typically separated from other urban centers and, relative to other urban

municipalities, have smaller populations, lower household incomes, and higher per capita local government expenditures. Predominately suburban municipalities, many from the Melbourne metropolitan area, form the remaining urban group. This group has large and relatively young populations, multiple population centers, rapid growth, and high household incomes.

Public expenditure characteristics in these groups exhibit distinctly different patterns. Per capita expenditures in rural municipalities average \$247 in contrast to \$165 in urban communities. Budget allocations are also quite different. Expenditures for general government and road maintenance represent almost two-thirds of the rural budget but less than one-third of urban. Road maintenance represents the greatest difference—less than one-tenth of urban outlays but one-third in rural municipalities generally and four-tenths in the rural shire subgroup. Together, expenditures for education, health and welfare, recreation and culture, and community amenities and economic services are one-fourth of rural budgets but one-half of urban outlays. Although smaller proportionately, the per capita expenditures for education, health, and welfare differ little between rural and urban municipalities. The same is true of "other" expenditures. The budget shares devoted to expenditure areas vary substantially between rural and urban municipalities and, to a lesser extent, among their subgroups. The analysis below seeks to explain that variation as a function of the relative cost of services in the communities and the expenditure level.

Because Victoria's municipal governments are not responsible for schooling, police protection, or social welfare, their role and budgets are more modest than is usually the case in the United States or Canada. Otherwise, the municipal authorities provide a conventional range of municipal services. Municipalities are governed by locally elected councils. In 1978–79, property ownership or occupancy restrictions implied that not everyone could vote in local elections. There is now universal franchise with special provisions for nonresident property owners. (For further discussion of the data and the institutional environment, see McMillan 1985.)

The Model

The indirect utility function is the foundation of this analysis. Utility is a function of commodity prices, P_i and the expenditure, M , on the bundle

¹ Cluster analysis was used to divide the 211 Victoria municipalities into the five classes studied here (McMillan 1983). Shire is the Victoria term for a rural municipality and is used here to designate the most rural subset of that group. In 1978, there were 133 shires in Victoria, most of which fall into the 111 rural group with almost all the others, on the fringe of major urban areas, fitting into the suburban category.

* The designations refer to expenditure categories as follows: (GEN) general government, (ROAD) road maintenance, (EHW) education, health and welfare, (REC) recreation and culture, (CAES) community amenities and economic services, and (OTH) other public services. Expenditure shares may not sum to 1.0 because of rounding errors.

of goods. The translog flexible functional form advanced by Christensen, Jorgenson, and Lau was chosen for estimation.

$$(1) \quad \ln V = \alpha_0 + \sum_i \alpha_i \ln(P_i/M) + \frac{1}{2} \sum_i \sum_j \beta_{ij} \ln(P_i/M) \ln(P_j/M).$$

The translog function serves as a local approximation of the exact (twice differentiable) indirect utility function about a point. Using Roy's Identity and maximizing utility subject to the budget constraint $M = \sum P_i X_i$, yields demand equations in expenditure share form:

$$(2) \quad \frac{P_i X_i}{M} = \frac{\alpha_i + \sum_j \beta_{ij} \ln(P_j/M)}{\sum_j \alpha_j + \sum_j \sum_i \beta_{ij} \ln(P_j/M)} \quad (i = 1, 2, \dots, n)$$

when $\beta_{ij} = \beta_{ji}$ in the indirect utility function (1) above.

For consistency with the assumptions of utility maximization subject to a budget constraint, (a) the substitution matrix must be symmetric (requiring $\beta_{ij} = \beta_{ji}$) and negative semidefinite, and (b) the demand functions must be homogeneous of degree zero in prices and expenditure which requires that $\sum \alpha_i = 1$ (a normalization) and $\sum_j \beta_{ij} = 0$ for each i . We maintain the symmetry restrictions and the normalization on α but test for homotheticity.

The system of equations to be estimated is limited to the set of local publicly provided commodities. In doing so, the demands for local public commodities are assumed a weakly separable branch of the utility function. This assumption is consistent with a two-stage decision-making process in which local households collectively decide how much to allocate to the local public sector and then how to allocate it among the various local public outputs. That collective provision is utility maximizing is maintained by the usual assumption (Bergstrom and Goodman) that public output is consistent with the preferences of the median voter.

One can speculate as to whether a utility maximization model is appropriate for the study of public outputs. Strong conditions are necessary if even aggregate private good data are to satisfy the predictions of consumer choice theory. The political processes involved in translating individual voter's preferences into collective choices are more complex and presumably argue for an

even more tenuous association with utility maximization. On the other hand, utility maximization based on the median voter model is now central to the theory of local public provision and has seen successful empirical applications (see Inman and Rubinfeld). Deacon, for example, provides a strong argument in favor of the utility-maximizing model. However, when the above conditions necessary for constrained utility maximization are tested, they are rarely fully satisfied. But then, similar tests of private good demands are frequently unsuccessful. On a more positive note, using a nonparametric test based on the generalized axiom of revealed preference, DeBoer and, to a somewhat lesser degree, McMillan and Amoako-Tuffour (1988b) provide evidence suggesting that the constrained maximization model may characterize the allocation of public expenditures.

Although estimation of flexible functional forms imposes minimal *a priori* restrictions on the underlying preferences, few studies have used this method in estimating the demands for public outputs (e.g., Dunne and Smith; Dunne, Pashardes and Smith; Hayes and Grosskopf; Grosskopf and Hayes 1983, 1986; McMillan and Amoako-Tuffour 1988b). Also, the single-equation approach usually used (Deacon and Perkins are exceptions) has meant that potentially important complementary and substitute relationships have generally been neglected. The system of equations resulting from the translog model employed here permits these to be recognized fully—and, as a result of the rural-urban disaggregation, even interjurisdictional differences. The indirect specification allows us to use information available on the prices of local public services in Victoria's municipalities.

Data

Systems of demand equations were estimated using 1978–79 cross-section data for the 211 municipal governments in Victoria, Australia. Measures of the costs (or prices) of local public services are a unique feature of the data. These measures are derived from unpublished data of the Victoria Grants Commission. As part of its procedure, the commission estimates the expenditure required for each municipality to provide a standard level of service. Allowance is made for intercommunity variations in (a) the number of units to be served ("expenditure needs") and (b) the local unit cost of the service ("expenditure disability"). Expenditure needs arise from

deviations from the standard measure of units to be served. For example, a disproportionately high share of population under the age of five implies greater expenditures for health services, and more kilometers of roads per property impose extra road costs. A disability allowance adjusts for unusual unit costs due to special difficulties in providing local services. The estimated expenditure requirements are discounted to reflect only the expenditure financed from the municipality's own revenues.² In 1980, assessments were made for eleven types of expenditures, which in the collection and analysis of the data were selectively combined into six expenditure categories: general administration (27.8% of the total); road maintenance (24.7%); education, health, and welfare (8.3%); recreation and culture (15.6%); community amenities and economic services (largely garbage disposal and street cleaning and lighting) (10.5%); and other (13.1%). The price or cost for each service is defined as the expenditure (specifically the amount financed locally) deemed by the commission as necessary to provide the standard level of service divided by the municipal population. This figure does not represent the unit cost of the service, but rather, the average price to the local taxpayer. Thus, the per capita cost of services as derived from the commission's estimates are relatively greater where the commission found exceptional expenditure needs or expenditure disabilities.

Such a measure of the relative price of public services is quite unusual, especially for local governments. (Deacon, and Blackley and DeBoer also established relative prices.) Typically in demand for local public good studies, the price to the decisive voter is based upon grants, tax share, and/or possible tax exporting.³ Assuming other governments maintain their sharing ratios, grants are already reflected in the price indexes. In this analysis, local tax share is uniform for all six categories of public services, so it does not affect relative prices. Similarly, although McMillan (1985) found evidence in this data of perceived tax shifting/exporting, such evidence does not change relative prices within a municipality and therefore will not influence budget shares. Thus, for an analysis of demand based on expenditure shares, relative price measures (as outlined here) are both necessary and ade-

quate in the context of the usual public sector prices.

Demographic variables (e.g., community characteristics) could also be incorporated in the model, e.g., Dunne and Smith. The work of Hayes (1986) and McMillan, Wilson, and Arthur suggests adding population. The extent to which population and other demographic characteristics reflect expenditure needs has already been incorporated into the price term. However, demographic variables might be added to pick up interjurisdictional variations in the private cost of consuming public services or to recognize possible taste differences. Efforts to incorporate demographic variables into this model encountered difficulties. However, McMillan (1985) found demographic variables in this data not very important in explaining per capita expenditures. Furthermore, Barnes and Gillingham found the introduction of demographic variables in a system of consumer demand equations inferior to using unpooled data. The division of this data into rural and urban (and the associated subgroups) achieves a degree of unpooling by demographic characteristics expected to be related to costs and tastes and rationalizes not including demographic variables here. Not incorporating demographic variables into the model results in the specification employed here being consistent with our earlier work.

General Empirical Issues

The demand system was estimated for each of the seven municipal classifications in table 1. Each system has six local public good categories, but restrictions require that only five equations be estimated.⁴ The equation for the other expenditure category (*OTH*) was excluded leaving the five equations for general government (*GEN*), road maintenance (*ROAD*), education, health, and welfare (*EHW*), recreation and culture (*REC*), and community amenities and economic services (*CAES*).

The system was first estimated with symmetry (i.e., $B_{ij} = B_{ji}$, and also the normalization $\sum \alpha_{ij} = 1$ and the equality constraint) imposed and again with the homogeneity constraint $\sum_j B_{ij} = 0$ added. The estimated parameters are not re-

² In determining its grant recommendations, the commission also considers revenue-raising capacity, population, and area.

³ See Inman and Rubinfeld for discussion. Alternatively, some use wage rates and labor shares (e.g., Hayes).

⁴ Because the budget shares must sum to unity, the disturbances are not independent so the six-equation variance-covariance matrix is singular. This problem is handled by arbitrarily omitting one equation. The system of the $n - 1$ remaining equations was then estimated using SHAZAM (version 5.0).

ported here but are available in McMillan and Amoako-Tuffour (1988a). The log likelihood values and test statistics of homogeneity conditional on symmetry are reported in table 2. The test rejects the homogeneity restrictions, a condition required for utility maximization, for all municipality classes but not for the small independent urban group. Although homogeneity is not rejected for one class, for consistency with the other estimates, the following results are from the models without the homogeneity restrictions.

The log likelihood values are also used to test the disaggregation of the municipalities into the various subgroups. Those tests indicate that the proposed subdivisions are justifiable (table 2). Informational inaccuracy values (Theil and Mnookin) support the disaggregation. The informational inaccuracy value (the mean accuracy) typically diminishes with disaggregation. Although public service price variations explain a large part of budget share differences among the total group, the greater homogeneity within subgroups reduces the overall inaccuracies of the estimates (McMillan and Amoako-Tuffour 1988a). These results substantiate the earlier conjectures that demands for municipal services are not alike among municipalities of different types. While the rural-urban separation was expected, finding the distinctions among the subgroups was surprising.

The expenditure and the uncompensated own-price and cross-price elasticities for the seven municipality groupings are reported in tables 3, 4, and 5. Elasticities were evaluated at the sample means using the elasticity formulas found in Christensen and Manser. The Allen partial elas-

ticities of substitution are reported in table 6, and the Morishima elasticities of substitution for the combined rural and combined urban groups are reported in table 7.

A Rural-Urban Comparison

The empirical results are discussed first for the two class rural-urban division. The discussion then turns to the disaggregation of the rural municipalities and finally for the subdivision of the urban municipalities.

Expenditure Elasticities

Except for the relatively low expenditure elasticity for other expenditures (about 0.3) for both the rural and urban groups, the expenditure elasticities in those two groups in table 3 range from about 0.6 to 1.6. The recreation and culture category has the largest expenditure elasticity at approximately 1.6 for both the rural and urban groups. Although there is some difference between the expenditure elasticities in the two groups, the levels are quite similar except for the community amenities category which has a value of about 1.27 for the rural group but 0.75 for the urban group. The nature of other expenditures, which include debt servicing and repair and restoration after natural disasters, likely explains its relatively low elasticity. This low value, as well as the range in the other expenditure elasticities reflects the merits of not imposing homogeneity which would restrict these elasticities to unity.

Table 2. Tests of the Homogeneity Restriction (log-likelihood values)

	Rural Shires	Rural with Decentralized Urban Centers	Rural (Combined)	Small Independent Urban	Suburban	Central Metropolitan Cities	Urban (Combined)
Symmetry ^{a,d}	504.9	577.6	1039.1	326.1	428.4	308.5	960.4
Symmetry and homogeneity	495.0	560.2	1020.9	321.6	396.6	296.0	940.2
Test statistic ^{b,c} (-2LLF)	19.8	34.8	36.4	10.0	63.6	25.0	40.4

^a The normalization $\sum \alpha_i = 1$ and the equality constraint ($\sum \beta_{ij}$ is the same in each equation) are also maintained along with the symmetry restriction, $\beta_{ij} = \beta_{ji}$.

^b The test statistic is minus twice the log of the likelihood function; i.e., $-2LLF = -2(\ln L_R - \ln L_U)$, where L_R and L_U are the likelihood values of the restricted (homogeneity and symmetry) and the unrestricted (symmetry only) models.

^c Six additional restrictions are required for homogeneity. The critical χ^2 values at the 5% and 1% level of significance with six degrees of freedom are 12.59 and 16.81, respectively.

^d These values are used to test the various disaggregations. For the division of all municipalities into the rural group and the urban group, for example, yields the test statistic 197.6 for 20 degrees of freedom from $-2\ln \lambda = [1039.1 + 960.4] - 1900.7$. The χ^2 test for further disaggregation of the combined rural and combined urban cases yields 85.2 and 205.2, respectively. The critical χ^2 values at the 5% level are 31.41 and 55.76 for 20 and 40 degrees of freedom.

^b Asterisk indicates an elasticity at least twice the standard error of the elasticity of the model with symmetry and homogeneity imposed

Deacon's study is the only other one familiar to us which reports expenditure elasticities for local public outputs. (Blackley and DeBoer, and Dunne and Smith report budget/expenditure elasticities for various state-local and national expenditures.) Although the functions he examines differ from the categories used in this study, with one exception (municipal courts at 2.10) the expenditure elasticities vary from 0.85 to 1.08. Income elasticities are commonly reported and are typically less than one (Inman). Expenditure elasticities of about one are not inconsistent with income elasticities of less than one because of the intervening effect of the elasticity of total local government expenditures with respect to income, a value which is typically less than one (Inman).

Price Elasticities

Uncompensated own-price elasticities of demand are reported in table 4. Unlike the expenditure elasticities, the own-price elasticities for the two municipal groups are less similar, appearing more inelastic for the urban municipalities with the exception of the general govern-

ment category. One positive own-price elasticity occurs in each group, but the values are close to zero. Only elasticities with the appropriate negative sign are believed likely to differ significantly from zero.⁵ For the two aggregated rural and urban classes, no own-price elasticity exceeds (absolute) 1.0.

Price elasticities reported in single-equation studies of local public services are generally inelastic, but they vary substantially across functions and among studies, perhaps partly because of differences in the definition of the price term. Comparison with other studies is impeded because the responsibilities of Victoria's local governments do not include schooling and po-

⁵ Elasticities in tables 4, 5, and 6 which are designated with * are at least twice the standard error of the elasticity estimated from the model with both symmetry and homogeneity imposed. The estimated elasticities are quite similar for the two models. With homogeneity, however, calculation of the standard errors of the estimated elasticities is straightforward (Binswanger) and is believed to be a reasonably reliable indicator of significance in this instance. Evidence on confidence intervals for the elasticities of substitution support this position (McMillan and Amoako-Tuffour 1988a). The significance of the expenditure elasticities cannot be approximated this way because they are constrained to 1.0 by the homogeneity assumption.

tution, it is reasonable that the elasticities of aggregated bundles of services would generally be (absolutely) smaller than those for the individual services.

Cross-price elasticities (table 5) are typically low. For these two groups, only one exceeds

0.5 (absolute) and almost one-half are less than 0.1 (absolute). This result is consistent with those of the two other studies reporting cross-elasticities, Ehrenberg and Perkins, but contrast with those of Dunne, Pashardes, and Smith, for United Kingdom government expenditures.

Elasticities of Substitution

The Allen partial elasticities of substitution are reported in table 6.⁶ For the urban group of municipalities, general government expenditure and expenditures in the various other expenditure categories (except for education, health and welfare) are substitutes. An especially high degree of substitution is observed with road maintenance. The substitutability between general government and road maintenance also exists, although at a more modest level, in the rural group, and is the only notable interdependency between general government and the other five expenditure areas. For the rural group, the large positive elasticities (all over 4.0) indicate a high degree of substitutability among education, health and welfare, recreation and culture, and community amenities and economic services.⁷ Within the urban group, outlays on education, health and welfare, and on community amenities and economic services are also substitutable ($\sigma_{EHW, CAES}^A = 1.62$), but the other two relationships are complementary. Otherwise, the elasticities of substitution are generally low for the two municipal groups suggesting that strong substitution or complementary relationships do not exist between local public sector outputs.

The Allen partial elasticity of substitution has

⁶ Each matrix is symmetric about the diagonal. For both groups, one value of σ_{ij}^A is greater than zero, indicating that convexity conditions are not satisfied at the point of estimation. Also, the monotonicity condition is not satisfied for these rural data.

⁷ These elasticities are surprisingly large. Deacon and Perkins observed substitution effects between fire and police protection. Perkins also finds some interdependency between health and sanitation outlays and between parks and recreation and libraries; these results conform with those observed here.

been criticized (e.g., Blackorby and Russell) as an imperfect measure of the elasticity of substitution. The crux of the problem is that the Allen elasticity, which is the ratio of the compensated cross-price elasticity to the cost share (i.e., $\sigma_{ij}^A = \eta_{ij}^c/s_j$), measures only how one commodity adjusts to the change in another's price. When there are more than two inputs, this does not allow for the adjustment of other commodities. Blackorby and Russell advocate the Morishima elasticity as more economically meaningful. The Morishima elasticity of substitution, which equals the difference between the compensated cross and own-price elasticities (i.e., $\sigma_{ij}^M = \eta_{ij}^c - \eta_{jj}^c$), measures how the ratio of commodities adjusts to a change in the price of commodity j . (See Chambers, chap. 3 for further discussion and illustration.) In order that the reader may better understand substitutability among commodities and appreciate the difference between the two measures, we report the Morishima elasticities for the rural and urban classifications in table 7. A complete set is available from the authors.

Morishima elasticities are generally not symmetric (i.e., the value depends upon which price changes) and Morishima substitutability/complementarity need not match Allen substitutability/complementarity. For the rural municipalities, only one elasticity ($\sigma_{REC, OTH}^M$) indicates complementarity, while ten did according to the Allen elasticities. In the case of $\sigma_{GEN, j}^M$, general government now substitutes for all other budget categories, but the elasticities of substitution for *EHW*, *REC*, and *CAES* are now somewhat larger. When the price of general government changes, $\sigma_{i, GEN}^M$, the relationship is somewhat stronger for

road maintenance (as before). With Morishima elasticities of 0.99 or larger, the substitutability among health, education and welfare, recreation and culture, and community amenities and economic services is less than reflected by the Allen measure but is still pronounced.

For the urban group, the extent of complementarity is again reduced by the Morishima measure but, as before, is concentrated in the education, health and welfare, and the recreation categories. Now, however, with the lack of symmetry, complementarity is concentrated only in the columns (i.e., $\sigma_{i, EHW}^M$ and $\sigma_{i, REC}^M$), where all but one of the signs match those of the Allen elasticity. General government and road maintenance continue to show greater degrees of substitutability with each other. Although the Morishima elasticities are smaller, the relationships among the education, health and welfare, the recreation and culture, and the community amenities and economic services categories are retained. Overall, while the Morishima elasticities tend to be smaller and indicate less complementarity than the Allen measures, important parallels remain in the two sets of results.

Two Types of Rural Municipalities

The rural group examined above is the combination of a group of rural municipalities with limited urban populations (rural shires) and rural municipalities with more significant urban development. For the two subgroups, the expenditure elasticities parallel each other except for the *EHW* and the *CAES* categories. In the case of education, health and welfare, the expenditure elasticity for rural shires, at about 0.5, is half that for the rural decentralized urban group; but for community amenities, at 1.4, it is about twice as large. The own-price elasticities are consistent for the two groups except that the value for the other expenditure category for the rural shires has a positive sign. The price interdependence between community amenities and economic services and various other expenditure categories for the combined rural municipalities seems to stem from a strong relationship in the rural shires. There, eight of ten of those cross-price elasticities are likely significantly different from zero, and six of those eight have a value in excess of (absolute) 0.5.

The Allen elasticities of substitution reveal some interesting differences. For all expenditure categories but road maintenance, the elasticities with general expenditures differ in sign between

the rural shires and the rural municipalities with larger urban populations, i.e., when they are substitutes in one class they are complements in the other. The substantial three-way substitutability found among the *EHW*, *REC*, and *CAES* categories in the combined rural group now separates into two patterns. In the more urbanized rural municipalities, a high degree of substitutability still exists between education, health and welfare and recreation and culture and community amenities; however, substitutability is not maintained between recreation and culture and community amenities. For the rural shires, the high elasticities of substitution between community amenities and education, health and welfare, and between community amenities and recreation and culture remain, but that between education, health and welfare and recreation and culture does not. Also, unlike in the aggregate rural case, road maintenance and the two personal services categories (*EHW* and *REC*) exhibit a considerably greater degree of substitutability in these two classes.

The model for the rural shires does not meet convexity conditions ($\sigma_{OTH, OTH}^A > 0$), but the model for the more urbanized rural municipalities does satisfy convexity. Also, monotonicity is not satisfied for the rural shires.

The Urban Municipal Groups

Three types of urban municipalities were identified in the five class categorization of the Victoria municipalities—central metropolitan cities, small independent urban municipalities, and suburban municipalities. With the exception of road maintenance, the expenditure elasticities for the central metropolitan cities and the small independent urban groups closely parallel each other.⁸ The expenditure elasticities for the suburban group tend to differ from the other two—those for community amenities and (especially) for recreation and culture are higher while those for the other expenditure category, for education, health and welfare, and (to a lesser extent) for general government are lower.

Only for the central metropolitan cities group are all own-price elasticities negative. Positive price elasticities occur in the suburban group for community amenities and in the small city group for the education, health, and welfare category

⁸ Recall that the homogeneity restriction, implying expenditure elasticities of 1.0, could not be rejected for the small independent urban group.

but are not believed to differ significantly from zero. Demands are generally price inelastic. In only two cases are values in excess of (absolute) 1.0 recorded, and only seven of eighteen exceed (absolute) 0.5. However, these elasticities vary considerably across municipal groups. Other than those for road maintenance, unlike the results for the rural categories, few elasticities are likely to differ significantly from zero.

The cross-price elasticities are generally low for these municipalities too. In only one case, between education, health and welfare, and recreation and culture in suburban municipalities, does the value reach one ($\eta_{CAES, REC} = 1.002$). Even when the values are relatively large, there is little consistency or pattern among the different municipal groups.

For the three classes of urban municipalities, a high degree of substitutability or complementarity (using the Allen measure) exists among expenditure categories, especially for the suburban and central metropolitan groups for which almost one-half the elasticities of substitution exceed absolute 1.0. However, except for the suburban group, few of these elasticities are likely to differ significantly from zero. The interdependence is particularly noticeable among general government and the other five budget areas. Only for general government and road maintenance and for general government and community amenities is the substitute relationship consistent across all three municipal groups. These elasticities are also quite large over the three municipal groups for the education, health, and welfare group; but, again, the signs are not uniform. Interdependencies occur among education, health and welfare, recreation and culture, and community amenities, but they are not consistent across municipalities.

Convexity conditions are not satisfied for any of the urban municipal groups, but monotonicity is met for all three groups.

Conclusions

Very little is known about the demands for local public services in municipalities of different types, and particularly about those in rural municipalities. This is so although there are various reasons for expecting demands to differ, especially between rural and urban jurisdictions. A system of translog equations was used to estimate the demands for six local public sector outputs in the kinds of municipalities spanning the full range found in Victoria, Australia. It was

found that demands differ between urban and rural municipalities and, somewhat surprisingly, even among the five categories comprising these two groups, at least to the extent that municipal budget shares can be explained by the local costs of provision and total expenditure.

The demand differences which exist are revealed in the elasticities and are usually most obvious between the rural and urban groups. For example, own-price elasticities tend to be more inelastic for urban municipalities and interdependencies between expenditure categories are stronger in the rural than in the urban (except for the suburban) groups.

Demand elasticities are both intellectually interesting and policy relevant. They are helpful to those attempting to explain or predict municipal expenditure changes. Price and expenditure elasticities are especially valuable to those projecting the impacts of tax changes, grants designed to promote certain kinds of expenditures, or grants to equalize fiscal capacities. Measures recognizing interdependencies among budget categories, as reported here, are also useful in efforts to predict the full implications of fiscal reforms such as the "New Federalism" (Craig and Inman), determine cost of public service indices (Deacon), or define more general measures of fiscal capacity (Akin).

The elasticities reported here are generally consistent with the (admittedly quite broad range of) elasticities reported in studies of local (and typically urban) government outputs. At the same time, the demands do vary among municipalities of different types. This result suggests that some of the observed variations in elasticities may result from differences in the type of municipalities, even among urban municipalities, studied. It also implies that greater attention should be paid to distinguishing the types of municipalities surveyed and that more analysis could be done of public sector demands in the classes of municipalities now underrepresented in the literature.

Distributional Effects of Household Linkages

G. Andrew Bernat, Jr. and Thomas G. Johnson

The study uses input-output models with disaggregated household sectors to demonstrate that important interhousehold linkages are ignored in standard input-output models of both rural and urban regions. The results indicate that higher-income households are not strongly linked to low-income households and that, given equal changes in exogenous income, low-income households will have much higher impacts on the local economy than high-income households. In addition, significant differences in household linkages were found between rural and urban regions.

Key words: household income, linkages, regional input-output models.

Knowledge of the linkages among economic sectors has long been employed in regional impact models, most notably in input-output (I-O) models. The level of sectoral disaggregation varies widely from model to model, with many models including considerable detail for at least some of the goods and service producing sectors. However, despite recent advances in modeling the household sector, most regional I-O models still treat the household sector as a single, aggregated sector. This treatment masks the complex linkages both among household groups within the household sector as well as between these household groups and other economic sectors.

The purpose of this paper is to demonstrate the large differences in household linkages in small, rural regions. Large differences in linkages according to household income indicate the need for models that can capture these differences (Johnson and Capps; Martin and Henry; Stevens and Trainer; Park, Mohtadi, and Kurbursi). The distribution of household linkages determines how a change in the income of one household group affects the distribution of income among all households. For example, trickle-down theory, in which spending by high-in-

come households leads to higher incomes for lower-income households, requires strong linkages between high-income households and low-income households. Finally, differences in linkages according to the level of development of an economy are important to consider as well. In order to analyze these issues, household linkages in four regions, three rural and one urban, of Virginia are examined.

The concept of household linkages is developed in the next section. The models are then discussed and the results presented, followed by a summary and conclusion.

Household Linkages

Two economic sectors are directly linked if one sector purchases goods or services from the other. Total linkages consist of both direct linkages and indirect linkages generated by the intersectoral relationships in an economy.

Households are linked to one another through income generation and induced spending. Two major characteristics of interhousehold linkages are magnitude (or strength) and distribution. Magnitude is the income received by the second household from an exogenous increase in the income of the first household. The total strength of linkages for a household is the sum of all increases in household income resulting from the initial increase.

The strength of linkage is greater for some households than others. This pattern of varying strength of household linkages reflects the dis-

The authors gratefully acknowledge helpful comments from Ken Hanson, Chinkook Lee, and Gerald Schluter.

tribution of linkages. In a uniform distribution, the strength of linkage from a particular household is the same to each other household; thus, a change in the income of one household would result in an equal change in the income of all other households. In contrast, nonuniform linkages would result in larger changes for some households than others. In an extreme form, trickle-down theory asserts that the linkages from upper- to lower-income households are stronger than the linkages from upper-income households to other upper-income households. Clearly, the distribution of linkages among households indicates how a change in the income of a particular household will affect the overall distribution of income.

If the linkages among households are not uniform, a change in the income of one household would have a different effect on the distribution of income than an equal change in the income of another household. Household linkages are not necessarily symmetric. Household *X* may be strongly linked to household *Y*, while household *Y* is weakly linked to household *X*.

The strength of total linkages between any two household groups is a function of three types of linkage: (a) the linkage between households and producing sectors as embodied in the household consumption function (consumption linkages); (b) the linkages among the various producing sectors of the region (interindustry linkages); and (c) the linkage between producing sectors and households (value-added linkages). The dependence of indirect household linkages on these three basic linkages implies that we should observe certain patterns in the strength and distribution of household linkages from region to region, as explained below.

First, the marginal propensity to consume (MPC) is usually considered to be a declining function of household income. Thus, a given marginal change in household income will result in a smaller total change in expenditures for high-income households than for low-income households. In a regional context, particularly for rural regions, the decline in MPC with income will be magnified if the regional share of the household expenditure bundle also declines as household income increases.

Second, if high-income households spend relatively more on services than do lower income households, and if the production of services is low-wage-intensive, high-income households would have stronger linkages to low-income households than would low-or middle-income households. A recent study of household link-

ages in West Virginia (Rose and Beaumont 1988) showed no support for trickle-down theory. Because of the similarities between West Virginia and the regions studied here, we also anticipate weaker linkages from upper-income households to lower-income households than from upper income households to other households.

Third, household linkages will be relatively weak in economies with weak interindustry linkages. With few interindustry linkages, a relatively small proportion of any change in the output of one sector will be transmitted to other local sectors. Thus, even if consumption linkages are relatively strong, a large portion of any increase in household expenditures will flow out of the region as demand for intermediate goods and services. Because rural regions have relatively weak interindustry linkages compared to urban regions of similar size, stronger household linkages are expected in more urban versus rural regions.

Finally, the dependence of household linkages on both value-added linkages and interindustry linkages means that linkages are distributed more uniformly, the stronger are interindustry linkages. If interindustry linkages are relatively weak, the distribution of household linkages for a given household group will be dominated by the distribution of value-added of the producing sectors to which the households have strong consumption linkages. If differences in value-added linkages across sectors are large, and if households have different patterns of consumption linkages, the distribution of household linkages will differ markedly across household groups. On the other hand, in an economy with strong interindustry linkages, a few sectors will no longer account for most of the value-added generated. As intersectoral linkages increase, the distributional impacts of each household group will converge to an overall weighted average of the value-added linkages of all sectors in the region.¹ If more developed, urban economies do have stronger and more extensive interindustry linkages than less developed, rural economies, household linkages will be more uniform in more urban economies than in rural economies.

To summarize, the expected pattern of household linkages within and among regions is expressed by four hypotheses.² First, total house-

¹ This is similar to Weisskopf and Wolff's concept of the convergence of inequality impacts.

² These hypotheses indicate the anticipated results of this study. However, they cannot be tested statistically because of the type of input-output models employed in the study.

hold linkages decrease with household income. Second, the distribution of household linkages differs among household groups. Specifically, the linkages of upper-income households are skewed toward middle- and upper-income households. Third and fourth, household linkages in rural economies are relatively weak and less equally distributed than the linkages in urban regions.

Modeling Household Linkages

Measurement and comparison of household linkages requires explicit modeling of the expenditure patterns and income flows of different household groups. The standard input-output model is inadequate because it treats all households identically. Therefore, the household sector of the standard Type II regional input-output model must be expanded. Following Miyazawa (see also Johnson and Capps; Martin and Henry; Rose and Beaumont 1989, 1988; Rose, Stevens, and Davis; Schultz; Weisskoff; Weisskoff and Wolff), such a model can be represented by

$$(1) \quad \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} A & C \\ V & O \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \begin{bmatrix} f \\ g \end{bmatrix},$$

where x is the vector of output levels of the n producing sectors in the region, A is the standard $n \times n$ matrix of technical coefficients, and f is the vector of final demand (excluding household demand) for the n producing sectors. This model departs from the standard I-O models by grouping the household sector into k income groups. Total household income, y , and exogenous households income, g , are represented by $k \times 1$ vectors rather than scalars. The consumption coefficients are represented by the $n \times k$ matrix C and the household value-added (income) coefficients are represented by the $k \times n$ matrix V .³

Solving (1) for x and y gives the matrix of multipliers:

$$(2) \quad \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} I - A & -C \\ -V & I \end{bmatrix}^{-1} \begin{bmatrix} f \\ g \end{bmatrix}.$$

Again following Miyazawa, (2) can be expressed in partitioned form:

$$(3) \quad \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} B(I + CKVB) & BCK \\ KVB & K \end{bmatrix} \begin{bmatrix} f \\ g \end{bmatrix},$$

where $B = (I - A)^{-1}$ and $K = (I - VBC)^{-1}$. Matrix B is the multiplier matrix of a Type I input-output model and indicates the change in the output of each producing sector required for a unit change in final demand of each producing sector, excluding the demand generated by households. The expression in the upper left portion of the multiplier matrix indicates the total change in sectoral output resulting from a change in final demand, including the induced effects of households. The elements of BCK , the upper right-hand portion, indicate the change in regional output that is attributable to an exogenous change in the income of each of the k household groups. The elements of KVB measure the change in the income of each of the k household groups due to a change in final demand (vector f) of each good and service producing sector.

Finally, the $k \times k$ matrix K indicates the direct plus indirect changes in income for each household group that would result from an exogenous change in income for each household group. The matrix K thus measures the multiplier effects (or linkages) within the household sector and is therefore the focus of our study. Each column of the matrix K shows the multipliers for a different household group. The first row shows the effects on the lowest income group, while the last row shows the effects on the highest income group.

The size and pattern of the elements of K indicate the linkage among households. Differences in the elements in any column j of the matrix K indicate a nonuniform distribution of linkages from households in group j to other households. For example, larger elements for low-income rows than for middle- or upper-income rows in the high-income columns of the matrix K would be consistent with trickle-down theory.

If the columns are not identical, linkages differ across household groups. Varying strengths of linkage across household groups are indicated if the elements in any row differ across columns. If the column totals differ, then the strength of total linkages differs by income. The sum of these totals is the analog of the household income multiplier of the standard Type II input-output model (Miyazawa).

Model Implementation

The study regions were chosen to compare different types of rural regions and to compare rural and urban regions. In particular, the regions

³ This formulation assumes no direct transfers between households. To model such transfers, the lower right-hand diagonal submatrix would be nonzero.

were chosen to represent a wide spectrum of industrial compositions and of income distributions. These considerations led to the selection of four regions in Virginia.

Regions 1, 2, and 4 are rural whereas region 3 is highly urban. The coal industry is the dominant industry in region 2, while regions 1 and 4 are primarily agricultural. Differences in either the strength or distribution of household linkages that result from differences in sectoral composition should be apparent because of the differences in economic structure represented by these regions. In addition, the hypothesis that the distribution of household linkages is a function of the degree of interindustry linkage, and thus regional development, can be examined by comparing regions 2 (the least developed region) and 3 (the most developed region). The distribution of income in region 4 is one of the most unequal in Virginia, whereas region 3 has one of the most equal distributions. Inequality in regions 1 and 2 is near the statewide average. These regions therefore permit examination of the relationship between inequality and the pattern of household linkages.

Each of the four models required the construction of matrices A , C , and V .⁴ The technical coefficients matrices, A , were constructed from a seventy-two-sector 1977 U.S. I-O model using the regional purchase coefficient method proposed by Stevens et al., of the Regional Science Research Institute (RSRI). The matrices of consumption coefficients, C , were based upon the Consumer Expenditure Surveys (U.S. Department of Agriculture, Bureau of Labor Statistics 1977a, b). The expenditure data for each of 12 household groups were converted from the 147 major commodity groups to the I-O sectors using a bridge matrix that was part of an input-output model of Virginia constructed by RSRI. The V matrix is based upon the Public Use Microdata (PUMS) tape from the 1980 Census of Population and Housing, a matrix of employment coefficients from the 1977 RSRI input-output model of Virginia, and Virginia Employment Commission data.

Analysis and Results

The most important characteristic of the K matrices to examine is whether the strength of household linkages differs across income groups.

Total household linkage for each household group is the column sum of the household multiplier matrix K . In all four regions, these totals are much lower for the higher-income groups than for the lower-income groups (table 1).

The differences in total household linkage presented in table 1 imply that aggregation of households into a single sector likely will introduce serious errors in the resulting multipliers, particularly when the impacts of exogenous changes in household income are considered. These results support the hypothesis that lower-income households are more strongly linked to the regional economy than are higher-income households.⁵

To facilitate comparisons of the distribution of household linkages, each of the four K matrices can be considered as a multiplier surface. The row and column axes represent household income groups, while the size of the elements of K represent the height of the surface. Each of the K matrices for the four regions exhibit certain regularities that can be quantified by estimating the following polynomial:

$$(4) \quad k_{ij} = b_0 + b_1i + b_2j + b_3i^2 + b_4j^2 + b_5ij + b_6i^3 + b_7j^3.$$

The dependent variable, the ij th element of K , is the change in income of the i th household group resulting from a dollar's change in the income of the j th household group. The row index of K is represented by i and the column index by j . The identity matrix was subtracted from each K matrix to allow examination of indirect effects alone. The diagonal elements of each multiplier matrix are composed of two parts. One part, called the direct effect, represents the tautology that an increase in the income of a household by a dollar raises the income of that household by a dollar. With no intersectoral or household linkages, the diagonal elements of these matrices would be unity. Because the immediate effect does not represent a linkage in any meaningful sense, it is removed by subtracting 1.0 from each element on the diagonal. The remaining portion of the diagonal elements measures the linkage of each household to itself. The results of estimating these equations using OLS are presented in table 2.

Equation (4) makes it possible to construct the multiplier surfaces and to clearly see how the distribution of the k_{ij} 's varies across rows, down

⁴ Further detail on both data sources and model construction is available on request and in Bernat (1985). Also see Bernat (1989) for an application of the model to income transfers.

⁵ This result clearly is a short-term result and ignores any long-run savings-investment linkages between households and the rest of the region.

Table 1. Total Linkages by Household Group

Group	Income (\$1,000)	Region 1	Region 2	Region 3	Region 4

^a Single asterisk indicates significant at the 10% level; double asterisk indicates significant at the 1% level.

columns, and between regions. For example, the hypothesis that the distribution of linkages across households differs by income would be supported if the coefficients on the terms which include the column index (the j 's) are significantly different from zero. A uniform distribution of linkages among households would be indicated by insignificant coefficients on the terms which include the row index. Finally, a hill- or trough-shaped pattern is possible when the coefficients on either the row or column indices are of different signs. A positive b_3 and negative b_1 and b_6 would indicate that the elements of the columns of K rise and then decline as household income increases, depending on the relative magnitudes of the coefficients.

The results of estimating equation (4) for each region indicate that the K matrix for each region exhibits a strong hill-shaped pattern down the columns. The coefficients on i and i^3 are negative, while the coefficients on i^2 are positive, indicating that the elements of each column of K first increase and then decrease as one moves

from low-income rows to higher-income rows. Thus, household linkages were strongest to the middle- and upper-middle income groups for all households. Not only is there little evidence of strong trickle-down effects, but the hill-shaped pattern for every income group in each region indicates that an increase in household income of any household group would have a larger impact on middle- and upper-middle households than on either upper- or lower-income households.

A second feature of the K matrices is that the elements of each row decline as one moves from low-income columns to high-income columns. In other words, the strength of linkages to each household group declines with income. The positive coefficient on j^2 for some regions indicates an increase in multipliers at intermediate income levels, with declining multipliers at the highest income levels. These results are consistent with the hypothesis that high-income households are not strongly linked to low-income households.

As an aid in visualizing the patterns implied by the above equations, the multiplier surface for the combined regions is presented in figure 1. The vertical axis gives the value of the ij th element of matrix K . On the j axis is plotted the income group index of the spending households (columns of K) and on the i axis is the group index of the receiving households (rows of K). The rear left-hand corner of the diagram (the origin in three-dimensional space) represents both the row and column for the lowest household group. The height of the surface above any line parallel to axis j gives the size of the multipliers from households in group j to households in group i .

Support for the hypothesis of little or no trickle-down effect is indicated by the hill shape of the surface along the i axis in figure 1, a pattern shared by all regions. For each household group, linkages are weakest to the household groups 2, 3, and 4. As household income increases (the row index increases, represented by moving from left to right in figure 1), linkages strengthen,

peaking with household groups 8–10, and declining steeply for the highest two income groups. Thus, the strongest linkages for all households, and in all four regions, are with middle- and upper-middle-income-level households.

This finding is consistent with the Rose and Beaumont's results for West Virginia. Their results indicate that the strongest linkages for each household group are with households in the \$25,000 to \$35,000 and \$35,000 to \$50,000 income classes. We found the strongest links with households in the three classes between \$21,000 and \$42,000.

The results also support the hypothesis that the strength of household linkages is positively related to the level of economic development. For each household group, the highest total multipliers were for region 3, the most developed, urban region (table 1). Region 2 had the weakest household linkages; this region is dominated by coal mining and in many respects is the most rural and least developed of the four study regions. Linkages for low income house-

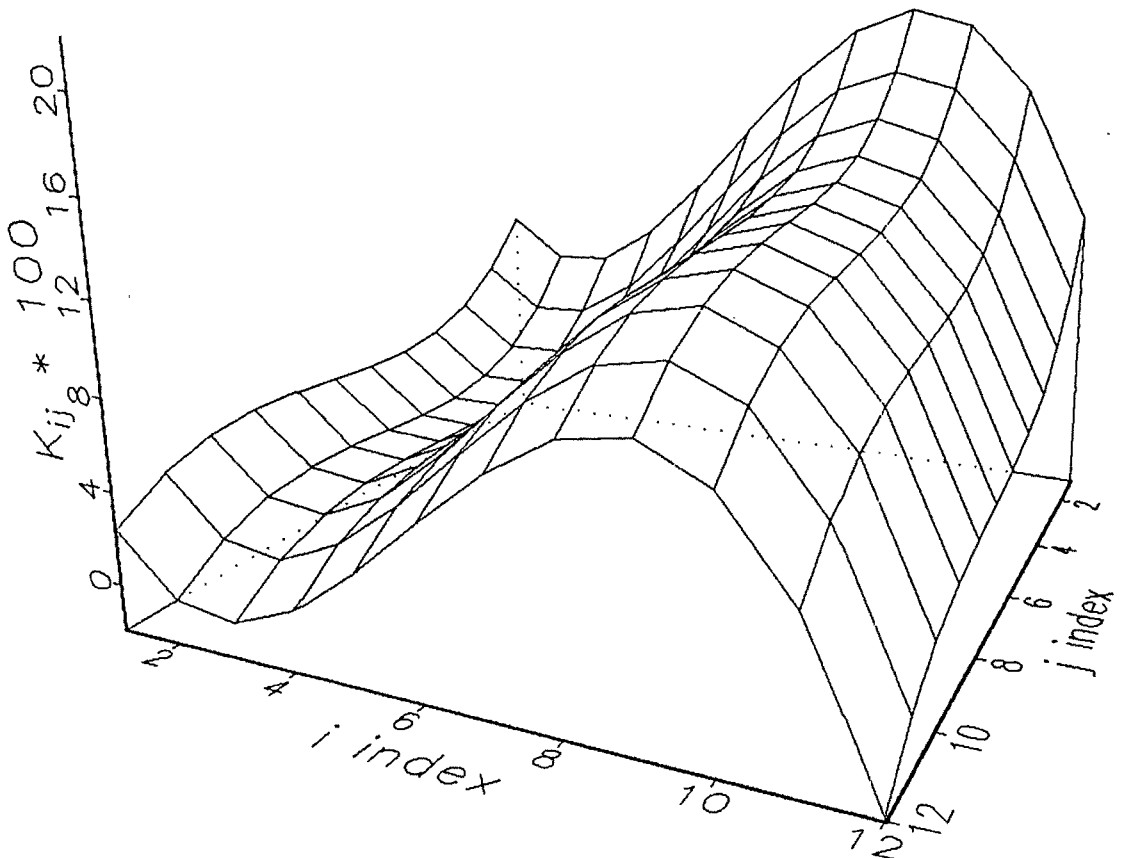

Figure 1. Multiplier surface for combined regions

holds in the coal region were 68% as strong as for region 3 and almost half for the highest income households. Total linkages in the two agriculture-based regions were similar to each other, ranging from about 92% of the region 3 linkages for low-income households to about 83% for high-income households.

In order to examine the hypothesis that household linkages are more uniform in more developed, urban regions, dummy variables for the urban region were added to the equation for the combined regions (d_1 , an intercept dummy; d_2 , d_3 , and d_4 are dummy interaction variables on i , i^2 , and i^3 ; and d_5 , d_6 , and d_7 are dummy interaction variables on j , j^2 , and j^3).⁶ The results in table 3 show that the intercept dummy and the three dummy interaction variables on terms containing the row index i are significantly different from zero; in contrast, the dummy interaction variables on the terms containing the column index are not significantly different from zero. The significance of these dummies indicate that the shapes of the urban and rural multiplier surfaces are significantly different.

These results also indicate that the absolute values of the coefficients on i , i^2 , and i^3 are closer to zero for the rural regions than for the urban

region. Thus, the urban surface has a steeper, more pronounced hill-shape surface, indicating that the differences in strength of linkage between middle-income households and other households are larger in the urban region than in the rural regions.

Summary and Conclusions

The results of this study demonstrate important interhousehold linkages that are ignored in standard regional input-output models. While these differences in household linkages are important when changes in exogenous household income are investigated, they will also affect the accuracy of sectoral multipliers. The results further indicate that higher-income households are not strongly linked to low-income households, at least in the four study regions. In addition, given equal changes in exogenous income, low-income households will have much higher impacts on the local economy than high-income households.

The results also indicate that more complex economies can be characterized as having much stronger linkages between households. The results indicate significant rural-urban differences in the level and shape of the multiplier surfaces but lend little support for the hypothesis that household linkages are more uniform in more developed economies than in the less developed, rural economies.

The disaggregation, by income, of the household sector in this study represents an important improvement over standard regional input-output models. While not a new technique, it has only recently been employed at the state level (Martin and Henry, Rose and Beaumont). Our study extends this work by demonstrating the feasibility of such a model for small, substate regions.

Economic Impacts, Value Added, and Benefits in Regional Project Analysis

Joel R. Hamilton, Norman K. Whittlesey, M. Henry Robison, and John Ellis

This paper addresses five issues encountered when estimating secondary benefits in regional project analysis: (a) the correction for opportunity cost of factors used, (b) the treatment of mobile factors, (c) the effect of economies of size, (d) the role of forward linkages, and (e) the role of spatial structure of economic regions. The first four are reasons that only a small part, if any, of regional impacts can be treated as regional net benefits. The fifth is a reason that, when secondary benefits or damages do exist, their correct estimation can depend on the spatial structure of the affected areas.

Key words: economic impacts, net benefits, regional project analysis.

Economists are often asked to assess the benefits or damages from a past or future event on the economy of some region. Examples include assessment of regional economic consequences of alternative timber harvest levels, entry or exit of a manufacturing plant, or the construction or demise of an irrigation project. Analysts have increasingly turned to the tools of regional analysis, especially regional input-output (I-O) models, to estimate these benefits or damages. Regional I-O models are constructed to estimate linkages among sectors of the economy of a target region. In this way, an event affecting one sector can be traced through the regional economy, and the change in value added, income earned by primary factors of production, can be estimated. This approach allows estimation of both direct impacts caused by the initial change in the affected sector and secondary impacts

which result as the direct spending works its way through the economy.

Direct income impacts of a project are the factor payments: the wages, rents, and profits earned by input factors used directly by the project. Secondary impacts result when the directly affected sector buys inputs from other sectors (backward linkages) or produces outputs that become inputs for expansion of other regional industries (forward linkages). A new irrigation project will cause agriculture to buy more from backward linked fertilizer, machinery, and insurance sectors, and may allow expansion of forward-linked livestock and food-processing sectors. The directly affected sector, along with backward and forward linked sectors generate value added consisting of income earned by the input factors. Thus, the available tools, including I-O models, allow us to estimate the impacts of the project or event on regional economic activity. The impact analysis is the easy part; the step that causes problems is translating these impacts into estimates of benefits or costs.

This paper addresses several methodological issues which arise and errors that are committed when estimates of regional economic impact are used to derive estimates of regional primary and secondary project benefits. Most of the issues noted in this paper apply whether the impact estimates are based on I-O models, economic base analyses, econometric models, or the cost ac-

counting commonly used in benefit-cost analysis. Some of these issues are noted in the regional analysis literature (Stabler, Van Kooten, and Meyer; Hamilton and Gardner), but we have found no comprehensive discussion of the issues. In fact, many of the more serious misapplications of these tools are not in the mainstream professional literature but in the myriad of environmental impact statements, forest timber plans, community development analyses, and other applied impact studies. These studies often represent the attempts of regional planners, semiprofessional economists, or project promoters to apply tools and concepts learned or mislearned from professional economists.¹ This paper addresses five related methodological issues.

First, it usually is a methodological error to use project impact on value added as the measure of project regional benefits or costs. Changes in value added estimated with an I-O model consist of changes in income accruing to regional primary inputs, which are at least partly offset by the opportunity cost of diverting these resources from alternative employment elsewhere in the regional economy. What portion of regional income impact represents actual regional net benefit or net damage from the event?

Second, because all factor income is paid to people, who may or may not move in response to the event being studied, there is an ambiguity regarding what income and whose income should be counted when computing primary and secondary regional project benefits.

Third, as the level of economic activity changes in the affected industries of a region, they shift to different points on their average cost curves. How frequently do the affected industries exhibit economies or diseconomies of size sufficient to result in significant regional benefits or damages?

Fourth, because a regional I-O model traces each sector's purchases from other sectors of the regional economy, it captures only the portion of secondary impacts caused by backward linkages from the event being studied. Under what conditions are forward secondary linkages also important and how can they be estimated?

Fifth, I-O models are usually based on political boundaries such as counties or states, while the functional economic areas within which impacts occur often cross political boundaries. What are the implications of this divergence for correct estimation of regional project benefits?

Opportunity Cost of Factors Used

It takes production inputs to support the economic activity associated with a project or event, including any backward and forward linked secondary activity. These production inputs have an opportunity cost. Using the division that is both convenient and common in the literature, this section will address only the direct income impacts and those caused by backward linkages; a later section will address forward linkages.

Benefit cost analysis commonly assumes full employment of most primary factors of production, perfect resource mobility, and absence of scale economies (Howe and Easter, p. 26; Margolis). If these assumptions apply to all factors, then, even though the value added impact might be large, benefits would be zero because all factors employed with the project could have received essentially the same returns in alternative employment without the project. In other words, the income impact resulting from project-related activity is exactly offset by the opportunity cost of the resources used.²

Most applications of project analysis do make specific departures from these assumptions of full employment and complete mobility. Often one input, such as the water used by an irrigation project, is considered underutilized and immobile. Thus the opportunity cost of this resource is low. In this case, when the project's direct impacts on value added are translated into direct benefits by subtracting the opportunity cost of the inputs used, the direct net benefits consist of the residual increase in returns earned by the previously underutilized resource. Thus, the residual returns to water, after subtracting the cost of all other project inputs, is often taken as an

¹ Just and Hueth; Just, Hueth, and Schmitz; and Cooke have addressed the measurement of welfare change in a series of forward and backward linked industries impacted by some event. While their theoretical development contributes to understanding the issues presented in this paper, it is not clear that their approach is generally empirically implementable for cases such as those discussed in this paper, nor is it likely to soon replace the I-O-based approaches.

² While not the usual case, some projects do cause inputs to be used or combined in new ways. Such technological change can enhance the productivity of resources above their opportunity costs outside the project. However, productivity enhancement benefits should be attributed to a project for only the short run. In the long run, the normal course of technology adoption should establish the enhanced productivity levels as the new regional norm.

estimate of the direct benefits of a water project.³

The assumptions of full employment and complete mobility can often be applied plausibly to all inputs used in generating secondary project impacts. Thus, regardless of the size of the estimated change in value added from secondary impacts, it may be exactly offset by opportunity costs of the inputs used, leaving net secondary project benefits of zero. This posture is especially plausible from a national accounting perspective and is codified in the "Principles and Guidelines" for water resource projects (U.S. Water Resources Council), which directs that project secondary impacts must not be included in "National Economic Development" benefits.

Using the rule that net benefits equal impacts less opportunity costs, additional primary or secondary regional net project benefits may result if factor prices and factor opportunity costs diverge such that unemployed or underemployed resources persist in the region because of barriers to resource mobility. Little empirical work has addressed the level and nature of resource unemployment needed to justify including such benefits in regional project analysis. The few studies which have addressed the issue have relied more on assumption than on analysis of real data. The most prominent is the work by Haveman and Krutilla, who studied the labor and capital inputs required for water resource construction projects. They concluded that the national opportunity cost of resources used directly and indirectly by such projects ranged from 69% to 94% of market value, depending on the type and location of the project. This conclusion implies that between 6% and 31% of the income generated by these projects could be counted as net benefits.⁴

³ Large projects may result in some input and output price impacts, but Young and Haveman stress that these impacts should not be confused with benefits: "Pecuniary impacts (usually called 'secondary' or 'indirect' economic effects) are those reflected in changes in incomes or prices caused by shifts in supply or demand. Pecuniary externalities are likely to represent income distribution rather than allocative effects, and their inclusion would amount to double counting" (p. 190).

A related argument is that projects which produce consumer goods confer benefits of increased consumer surplus. Such benefits can occur in regional project analysis only if the additional production lowers local prices and a large portion of the product is consumed locally. Of course, the loss of producers surplus (value added from the depressed local prices can equal or exceed the consumer benefits which accrue to regional consumers. Such price change effects are difficult to address within the fixed price context of I-O modeling.

⁴ In the context of benefit-cost accounting, project gross benefits are unaffected by whether some of the factors used were otherwise underemployed or unemployed. However, the difference between the factor prices and their opportunity cost is a "credit" offsetting

In his *ex post* study of the Colorado-Big Thompson water project, Howe (1987) assumed that 20% of capital earnings and 23% of wages and salaries represent net benefits. Hamilton and Gardner assumed that 10% to 20% of secondary value added by new irrigated agriculture in southern Idaho could be counted as net secondary benefits. In neither case were these assumptions based on empirical analysis.

Howe and Easter argue that if a region is highly dependent on a vulnerable industry and resources are immobile, then a much larger part of the value added resulting from a "rescue" of that industry can be counted as net benefit. However, Howe's "rescue" conditions will rarely, if ever, be met in practice. Even in Howe's negative impact scenario most of the released resources, except for some undepreciated immobile fixed assets, will eventually find other employment. The lifetime of most projects will be long enough to allow resources to move to their best use and to negate cyclical unemployment as an argument for secondary benefits. Even when short-run employment benefits exist, they can rarely be justified over the entire project life.

Most cases justify conclusions such as those reached in a chapter written by Hanke and Walker in the book by Haveman and Margolis: "Since there is no evidence that the conditions put forward by Margolis exist in the prosperous Mid-State area, secondary benefits have been eliminated from the analysis because they represent pecuniary transfers and not real effects" (Hanke and Walker, p. 343). Stabler, Van Kooten, and Meyer say: "Disregarding the possibility of declining long-run average cost curves in linked activities within the region, the general case for calculating secondary benefits on the basis of employable and immobile resources in Western North America is weak" (p. 20).

The burden of proof is on those who claim that a project uses labor or capital which would be unemployed without the project, therefore justifying the existence of secondary regional project net benefits, or the inclusion of additional value-added components in primary regional net benefits. Under most circumstances, the convergence between input prices and their opportunity costs restricts project direct regional net benefits to the residual returns to some particular underutilized target resource, such as the

some of the factor payments charged in the project cost account. Thus employment generation should not be counted a project benefit, but access to otherwise underutilized resources can reduce project cost, contributing to project net benefits.

water used by an irrigation project. Similarly, only a small portion (if any) of secondary income can be counted as secondary regional net benefits.

Treatment of Mobile Resources

Changes in direct and secondary regional economic activity of the kind discussed above usually result in some interregional movement of labor and capital. All factor income, whether earned by labor, capital or land, is paid to people. However, the people who receive that factor income do not always move in the same pattern as the labor and capital resources themselves. This results in a problem in deciding whose income counts when regional project benefits or costs are computed. This problem relates to the issue of accounting stance discussed in Stabler, Van Kooten, and Meyer.

The two polar possibilities are to count all or to count none of the income earned by immigrant resources. By definition regional income is the sum of the incomes of all residents of a region. Thus, the "all" posture would compare the sum of incomes accruing to everyone who would have lived in the region without the project and sum of incomes of everyone who will be living in the region with the project—with the difference proposed as an estimate of regional project benefits. While this approach occurs frequently in the project analysis literature, we question its validity.

The "none" alternative of not counting any of the income received by immigrants was advocated by Howe:

The water manager . . . should act in the interests of the existing population of his area unless he receives policy direction from his constituency to the contrary. This point of view is the same as that taken by corporate financial managers in deciding the merits of new investments or stock issues, and is expressed in the question, 'Will the action dilute or enhance the equity of existing stockholders?' If this stockholder equity view were taken by city managements in general, continued urban growth might be seen in a different light. (page 12)

Similar positions were stated by Hamilton and Gardner:

Insofar as regional project evaluation is concerned, it is the differences in value added generated by resources that would be in the region in the absence of the project which are relevant. It is debatable whether wages and salaries going to imported labor

and returns to capital provided from outside the region (while a part of gross regional product), are valid regional benefits to those people who would have been residents of the region without the development. (page 8)

And, again, we see agreement in this statement by Keith and Glover:

There is considerable controversy concerning the payments to imported labor as a regional benefit. If workers are transient, then long-term changes in payments to labor are not likely to result in large gains to the local economy. As long as it is a permanent change, imported labor represents an increase in resident population and household income. However, these benefits do not necessarily accrue to the population which was resident in the region prior to the project development, even though a substantial part of increasing service costs (such as schools, roads, etc.) and/or other costs (housing, food, etc.) may be borne by current residents. Thus there is a choice between estimating benefits to existing or to projected populations. If regional population growth is desirable, or is a direct goal of a project, then perhaps benefit estimates should include net income to permanent immigrants in the benefit calculations. However, any increasing costs of consumer goods or public services should be netted from the calculated benefits. It is highly doubtful that payments to imported capital will be paid to residents of the local community. In order to be as conservative as possible, to avoid counting benefits which may be fugitive (i.e., may not remain in the region), and to minimize the problems of calculating increases in, and distribution of, increasing social costs, it is recommended that only benefits accruing to current residents of the region be calculated. (page 22)

Consider an example. Assume that the impact of a new project causes someone from another community to take a new job in your community. Further, assume that the migrant's previous employment income was \$30,000 per year and that person now earns \$40,000 in the new job. Note that the aggregate accounting region consisting of both donor and recipient communities together has clearly experienced a \$10,000 benefit; and \$40,000 income increase in one community offset by a \$30,000 opportunity cost in the other. However, from this aggregate accounting stance incorporating both the mover's origin and destination, no net resource migration has occurred.

The problem arises in measuring the benefit of this move to your community. Certainly the new individual's local spending for consumption or investment will stimulate local businesses, and some of this induced income may find its way to the residents of the community.

Other than this induced effect from respending, however, neither you nor other original members of your community benefit from the \$40,000 income per se. Similarly, the remaining residents of the community that lost \$30,000 employee may suffer some income loss because respending of this income has stopped, but they do not feel the loss of the \$30,000 per se. It is the migrant alone who is the direct beneficiary of the \$10,000 increase in factor payments.

Whose welfare should be included within the accounting stance used to determine the well-being of the region? To what extent does well-being of neighbors, especially new neighbors, enter into an individual's welfare function? For such questions economic theory can give little guidance. One plausible approach for a recipient community inclined to value growth is to count the \$10,000 income net of opportunity cost (but not the entire \$40,000 income of the migrant) as a net benefit. This is the benefit to the community residents from a happy new resident who has just experienced a \$10,000 income increase. For the donor community, the emigrant may be out of sight and out of mind. Realistically, migrants are neither completely included in nor completely excluded from the community accounting perspective. The accounting stance advocated by Young and Howe, Hamilton and Gardner, and Keith and Glover would eliminate all direct benefits consisting of immigrant wages and count only benefits accruing to previous residents.

It is important to examine the assumptions implicit in this example. First, a \$10,000 increment between donor and recipient regions could not coexist with full employment and perfect factor mobility. Second, if such a differential between the two regions did exist, it could only persist in the short run, supported by a labor immobility that the migrant has managed to overcome. In the longer run, either wages in the donor region will be bid up by continued out-migration, or wages in the recipient region will be depressed by continued immigration. Thus, the benefits to the recipient region attributable to migrant wage changes should be either non-existent or short run.

What about the induced effects from the respending of the migrant's \$40,000 income in the destination region? Clearly, as noted in the previous section, the multiplier effects will generate further secondary regional income. However, this increase in economic activity will draw resources away from alternative employment, so the opportunity costs of these resources must

be deducted. Moreover, the induced effect will very likely be supported by the immigration of additional labor and capital, aggravating the problem of deciding whose income to count.

The situation is clearer for transient migrant labor. Income earned by labor that resides only temporarily in a region, while by definition a part of regional income, is certainly not valued very highly by other regional residents except as its respending induces activity elsewhere in the regional economy.

Similar problems are encountered with mobile capital. A new project will have both primary and secondary impacts on regional capital use and income. If internally owned capital is used, it has an opportunity cost equal to its value in its best alternative use. Inflows of monetary capital are not per se a regional benefit. It is the investment of this money in physical assets and the subsequent productive use of these assets that will generate regional incomes. However, capital attracted from outside the region, does not have zero cost, as implied in Howe (p. 79): "Insofar as these productive factors, including capital, are attracted from outside the project region, the loss of their outputs elsewhere will not be counted as costs in the project region's assessment of the project." Howe fails to note that importing this capital probably does not change its ownership. The price of importing capital to a region is the outflows of interest payments and profits sufficient to attract the capital, which is its exact monetary cost in the importing region and should approach its opportunity cost in the exporting region. Even for projects funded by government grant, this capital may have an opportunity cost in terms of other regional projects not funded (congressional logrolling also has its limits).

If a project attracts both capital and its owners as immigrants to the region, this clearly has a positive impact on regional income. The situation is similar to that for immigrant labor—one can question whether increases in profit and interest payment accruing to immigrant capitalists are per se a regional benefit. The existence of regional benefits depends on whether this new profit and interest income satisfy growth goals of the original community residents, and whether they can capture benefits from the economic activity induced by the local respending by the immigrant capitalists.

Another aspect of migrant resources is the impact that immigrant resources can have on local production processes. Immigration of labor or capital might enhance the productivity and re-

turns earned by local labor and capital. These are potentially important project benefits, which unfortunately are poorly modeled by fixed coefficient approaches such as I-O models. More research could productively be directed toward developing proper methods of incorporating these resource productivity benefits into project analysis.

Because much of the impact of projects is on income earned by immigrant labor and imported capital, this is one further reason the portion of estimated income impact, both primary and secondary, that can be considered a regional net benefit ranges from small to none.

Economies of Size

Reference was made above to changes in industry size as a justification for additional project benefits. In one sense, this is another way of viewing the underemployment/unemployment issues discussed above. Established firms in the region (the grocery store, the motel, the fertilizer dealer, the public school, and even the municipal government) may have adequate physical plant and labor to handle some increase in business. Similarly, on the downside, some decline in business may be accommodated without exit of labor or capital. Firms with considerable fixed labor or capital almost surely exhibit short-run size economies. On the other hand, if a firm's labor and capital can accommodate an expansion, then they must previously have been underemployed, or if the firm can tolerate a downturn without releasing labor or capital, that labor and capital must then become underemployed. In the long run, fixed assets must be replaced, and labor will move, ending this kind of short-run size economy benefits.

The issue goes beyond the fixed input/underemployment relationship. Long-run size economies may mean that a larger firm is better able to utilize labor or capital or has better market access than a small firm. Expansion of an industry may also result in agglomeration economies. Thus, an irrigation project might make possible the expansion of a livestock industry sufficient to give the meat-processing industry a cost advantage over competing regions. Regional growth may allow establishment of larger size, lower cost grocery stores, giving consumers the benefit of lower cost food.

On the other hand, any benefits flowing from industry size economies may be offset by other affected industries with either long- or short-run

size diseconomies. Power generation in the Pacific Northwest experiences an increase in average cost as demand grows; present generation is based on cheap hydropower methods, while increases will have to come from expensive thermal sources. Expanding firms that need to add or replace fixed assets may operate only at costs above those of an established firm with depreciated fixed assets.

Because the I-O model is based on fixed coefficients, it is of little use for estimating size economy impacts. Attempts to estimate these impacts must be based on calculations external to the I-O model. Little empirical research has documented the role of economies of size in the affected industries as a determinant of the regional benefits or costs of resource development projects. Among the exceptions are work by Whittlesey et al., and Findeis and Whittlesey. They considered the incremental costs of providing energy supplies, incremental farm capital needs, and incremental social overhead costs associated with irrigation expansion.

Economies of size is a possible source for both primary and secondary project net benefits. However, because the fixed-coefficient I-O model is unable to incorporate size economies, it cannot be used to estimate these benefits. Further, the possible existence of size economies is not a valid justification for including I-O based estimates of secondary impacts as benefits. This is another area where research could be fruitful.

Forward Linkages

Forward linkage impacts occur if output from the directly affected sector serves as input to some other sector, thus changing the output level of that sector. For example, a new irrigation project may increase feed grain production, promoting an expansion in the regional livestock industry, which in turn could result in more meat processing in the region. As with backward linkages, some of the regional secondary income impacts produced by forward linkages may be valid components of regional secondary net benefits.

The I-O model, because it traces purchases of each sector from all others, is well suited for translating a primary impact on one sector into estimates of the secondary impacts on production and value added by the backward linked sectors of the regional economy. Backward linkages are sure to exist—production requires inputs, so changes in production will be felt by

sectors that supply those inputs. Forward linkage impacts are far less certain. If a region produces more feed grain, there is no assurance that regional livestock production will expand. If a region produces more logs, there is no assurance that they will be processed locally into dimension lumber, plywood, or houses.

Regional forward linkages exist only if the forward industries are otherwise constrained by input shortage and their expansion is a viable, profitable proposition. Often, the expansion potential of forward linked industries depends more on the regional and national market conditions for their outputs (meat, houses) than on the regional supply of raw inputs (feed grains, logs). If circumstances are unfavorable for the expansion of forward linked sectors, several possible scenarios exist. First, the raw product may simply be exported from the region. Second, especially for products that are hard to transport long distances, the increase in raw material production in the project area may cause regional declines in product prices, leading to offsetting production declines inside or outside the accounting region. Third, forward linked activity using inputs produced in the project area might increase, but an offsetting demise of such processing activities could occur elsewhere in or out of the region. For the first two scenarios, no regional forward linkage impact would occur. For the third, any regional impact occurs through transfer from another region.

The weakness of forward linkages is recognized by Hamilton and Gardner:

Certainly some of the output of newly developed land will be fed to livestock, other crops from this land will be used as input to food processing plants, and these secondary activities will generate secondary value added. However, the demand for regional exports of processed food and livestock products is quite inelastic and driven largely by factors outside the region. We question the extent to which new irrigation actually increases the total amount of secondary food processing or livestock production in a region. Development may only mean that new farms rather than the farms present without development will supply a share of the inputs to these secondary activities.

(page 8)

Due to inelasticities of crop demand, the net effect of new irrigation on state crop acreage has historically been an increase in small grain and forage crop acreage with little increase in the acreage of higher valued crops. Essentially the acreage of high valued crops displaces existing acreage of these crops. (This treatment conforms to the federal Principles and Guidelines which mandate that returns to high

valued specialty crops not be counted as part for the direct benefits of a water resource project.)
(page 5)

This same weakness is recognized by Howe:

There is no question that the availability of project agricultural outputs and the related demands for inputs led to the expansion of both forward (output processing) and backward (input supplying) linked activities in the project region. The sectors that are strongly forward linked to agriculture in the region are livestock and food processing. The markets for these final products are found almost completely outside the C-BT project region. It seems reasonable to argue that, had C-BT not existed, the additional supplies of these final products would have been produced elsewhere in the western United States. For this reason forward linkages can be ignored when computing net income changes from the national accounting stance, although not from the project region stance.

(page 88)

If a project does cause secondary forward linkage impacts these will be in the form of output changes in other sectors and income earned by the production inputs used. The amount of this income impact that counts as regional benefit depends on the same opportunity cost considerations outlined for backward linkages. Labor and capital income impacts generated by forward linkages count as benefits only to the extent that the return in the new use exceeds its opportunity cost in its alternative use, and if some of these returns are captured by the permanent residents of the region. This will only be true if unemployment and immobility of labor and capital are substantial.

Young and Howe outline steps necessary to properly incorporate forward linkages into analysis of regional project benefits in instances when this is justified by market conditions and profitability of prospective industries. To estimate regional forward linkages if sector A increases output of raw material by Q_A , they note that one should:

- a. check the structure of local industries to see whether or not forward linkages appear likely;
- b. calculate the added processing output, Q_P , that is likely to follow from the availability of Q_A ;
- c. insert Q_P in the input-output (inverse) model to determine what output changes will be required from all sectors other than that containing A;
- d. calculate the increased factor payments (i.e., to labor (households), rent, interest, profits) that the model predicts to follow from the increased output in all sectors other than A;
- e. estimate the opportunity costs of these newly employed factors to the state and subtract them from

the increased payments calculated in (d) to get secondary net benefits. (page 69)

The issue is whether forward linkages exist, whether they fall within the accounting stance, and how they should be treated in empirical project analyses. We have outlined conceptual reasons that forward linkage benefits may be nonexistent or small. We conclude that the existence of forward linkage benefits must be justified empirically, case by case, using procedures like those outlined by Young and Howe.

Spatial Diffusion of Secondary Impacts

The above discussion has taken the project region as an internally undifferentiated partition of a uniform landscape. However, in the well-known sense of central place theory (Christaller, Losch), economic regions exist quite apart from the political regions superimposed on them, and these economic regions have a hierarchical internal and external trade structure. Regions used for input-output modeling are typically based on political units (states, counties, multistate or multicounty aggregates), easing data and model-building problems, and because the questions asked are usually framed in terms of political units. Both the trade patterns and the divergence between the boundaries of political and economic regions have consequences for regional project analysis.

Seninger noted that there may be clear policy and planning implications from an analysis of spatially diffused secondary impacts among a system of communities. Disaggregating impacts of a project to the community level may be helpful for understanding the nature of the impacts, planning how to deal with them, and deciding who should pay for them. By integrating central place and I-O theory, through an intercommunity I-O model (as in Robison and Miller), it is possible to trace the diffusion of secondary impacts through the central place hierarchy within a study region.

Ideally, I-O analysis should be used to model the economy of one or a hierarchical aggregation of functional economic areas (Richardson).⁵ When an I-O model is shoehorned to fit

the political units of data availability or to match the political boundaries of policy issues, the common nonsurvey techniques used to build these models can result in biased estimates of secondary project impacts (Robison and Miller). Economic impacts do not stop at political boundaries but usually spill across these boundaries into contiguous parts of a transcending economic region. The concept of interregional spillover is another way of looking at economic leakages from a region. Generally, small and less self-sufficient regions will have lower output and income multipliers because more spending leaks or spills into adjacent regions.

One can get a feeling for the spillover relationship from the output multipliers presented in table 1, which are based on the nested set of consistent I-O models from Hamilton and Jensen. As expected, Australia had the largest multiplier. The state of Queensland had a smaller multiplier because some secondary activity spills across its borders into other states. We can assume that each dollar of primary impact from some event in Queensland is associated with \$0.71 of secondary impacts, the same ratio as for events elsewhere in Australia. However, Queensland captures only \$0.55 of these secondary impacts while \$0.16 of secondary impacts spill over to other states. The ratio of spillover secondary effects to those captured by the region is the spillover coefficient, $0.16/0.55 = 0.291$ for Queensland. Moreton Region, containing Brisbane, the state capital, strongly dominates the economy of Queensland, allowing little of the secondary impacts from an event in that region to spill into other regions of the state. In contrast, an event in Toowoomba, a smaller town in Moreton Region, generates much more spillover secondary impacts than local secondary effects because it is so small and so strongly dominated by metropolitan Brisbane.

Interregional or multiregional I-O models (Miller and Blair) are appropriate analytic tools in cases where spillover effects likely are im-

Table 1. Australia Interregional Spillover Coefficients

Region	Average Output Multiplier	Spillover Coefficient to Next Higher-Order Region
Australia	1.71	
State of Queensland	1.55	0.291
Moreton Region	1.54	0.019
Toowoomba City	1.10	4.400

⁵ In the 1970s, the U.S. Department of Commerce, Bureau of Economic Analysis (1975, 1982) relied on hierarchical trade and central place principles to map the economic boundaries of the United States. The BEA aimed at delineating a complete set of functional economic areas for the United States (see also Fox and Kumar). BEA Economic Areas generally have a "Standard Metropolitan Statistical Area" at the center, surrounded by a number of hinterland counties. While the BEA areas follow county boundaries, they often cross state boundaries to define a region comprising parts of two or more states.

portant. This framework explicitly models both the structure of each regional economy and the linkages between regions. In this way, the impact of an event in one region can be traced to all other regions. Such a multiregional model was constructed by Carter and Ireri as part of a study of the impact of California-Arizona water reallocation alternatives. Their results, shown in table 2, can be interpreted in terms of spillover coefficients. These results indicate that for each dollar of secondary impact generated in Arizona, an additional spillover of secondary impacts ranging from \$0.058 to \$0.822 will also occur in California.

The consequences of interregional spillovers can be important in regional project analysis. Miller examined the possibility that spillovers could be the basis of interregional feedback, where development in one region can spill over, stimulating development outside the accounting region, which in turn spills back to further stimulate economic activity in the first region. If such feedbacks are significant, an I-O model would underestimate the extent of project impacts.

The recent Pecos River case in the U.S. Supreme Court (482 U.S. 124, 1987) illustrates another kind of spillover relationship based on a resource allocation conflict between two ad-

jacent political regions with an interlinked (nested) economic structure. In this case, if the accounting stance were based solely on the political boundaries, ignoring the hierarchical economic connections between the two areas, incorrect policy conclusions could easily result. The damages suffered by Texas for past underdeliveries of water by New Mexico under the Pecos River Interstate Compact include direct and secondary income losses net of the opportunity cost of the resources used. However, New Mexico would have had to reduce its irrigated acreage by at least 20 acres for each additional acre that could be irrigated in Texas. The 20 to 1 ratio is a consequence of the lags in the groundwater hydrology of the region, the evaporation losses, and the salinity buildup of Pecos River water delivered to Texas. The economies of the affected part of New Mexico are closely tied through strong forward and backward linkages to the adjacent parts of Texas. The question is: What would have been the net benefits to Texas if it had received the water and the direct and secondary impacts which that implies, but at the cost of losing spillover benefits because of the associated reduction in New Mexico irrigated acreage?

It is interesting to note that the two New Mexico counties which would have lost irrigated acreage under compact compliance are designated by BEA as part of the El Paso, Texas, functional economic area. The Texas-New Mexico border runs neatly between these New Mexico counties and the El Paso, Texas, SMSA that is the principal central place in this functional economic area. Because of the obviously close economic ties between these portions of New Mexico and Texas, actions taken in New Mexico should have large spillover effects in Texas. In this case, there is a real possibility that the spillover benefits accruing to Texas from using the water in New Mexico would exceed the direct and secondary damages of not having the water to use in Texas, leaving Texas better off because it did not get the water. However, if analysis was based on separate I-O models of the affected New Mexico and Texas areas, ignoring the economic linkages between the two, these potentially important spillover effects would remain hidden.

Note the internal consistency; if factor opportunity cost were 100% of factor market cost, then there were no secondary benefits to New Mexico from using the water and no spillover benefits to Texas; however, if factor unemployment or immobility is invoked to justify sec-

Table 2. Secondary Impact Spillover Coefficients from Arizona into California

ondary benefits, then spillovers are also a possibility.

The divergence between the political regions often used for regional modeling and the functional economic areas in which economic activity actually takes place sometimes causes analysts to incorrectly specify their accounting stance, resulting in biased estimates of project impacts and project benefits and missing important benefit spillovers between accounting regions.

Conclusions

This paper has addressed five issues that are encountered when estimating secondary benefits in regional project analysis: (a) the proper correction for the opportunity cost of factors used, (b) how to treat mobile factors, (c) the effect of economies of size, (d) the role of forward linkages, and (e) the role of the spatial structure of economic regions. The first four issues serve as reasons only a small part, if any, of regional impacts can be treated as regional net benefits or costs. The fifth is a reason that, when secondary benefits or damages do exist, their correct estimation can depend on recognition of the spatial structure of the affected areas. All five serve as cautions to the project analysis practitioner and as challenges for future conceptual and empirical research.

Technical Change, Land Quality, and Income Distribution: A General Equilibrium Analysis

Ian A. Coxhead and Peter G. Warr

This paper investigates the distributional effects of technical progress in agriculture. A small computable general equilibrium model is developed in which agricultural production occurs in two environments with fixed land resources of different quality. The analytical structure permits not only the rate but also the factor biases of technical change to differ between environments. Distributional results are generated for several classes of households distinguished both by their ownership of factors and by their consumption patterns. The results demonstrate that technical change produces distributional outcomes which are highly sensitive to its factor biases and to prior differences in land quality.

Key words: general equilibrium, income distribution, Philippines, technical change.

The quality of agricultural land, particularly access to irrigation, is a major factor influencing the rate of return to adoption of new technologies by farmers in developing countries. The development of new biological technologies, such as high-yielding varieties of rice, has focused on irrigated environments, where the likelihood of substantial yield increases has been highest. Accordingly, in most Asian countries, the yield gap of staple crops like rice between irrigated and less favorable environments has widened over the last two decades (Lipton and Longhurst).

Virtually since the beginning of the green revolution, concern has been expressed about the income distributional implications of the observed unevenness in the rate of growth of agricultural land productivity. The possibility that new technologies might adversely affect income distribution arises because irrigation systems are typically large and costly engineering projects. In any length of run shorter than that required for their construction, agricultural land is specific to a particular environment, irrigated or

unirrigated. The microeconomic theory of general equilibrium changes in the relative returns to sector-specific factors under a variety of exogenous shocks is well developed (Jones, Jones and Easton). The specificity of land has been exploited in a number of partial equilibrium analyses of technical change and income distribution (Evenson, Quizon and Binswanger 1983). General equilibrium models of agricultural development continue, however, to treat agricultural land as homogenous and farmers as equally affected by technical progress (Bautista, Quizon and Binswanger 1986).

This paper investigates the income distributional effects of technical progress in the agricultural sector of a small open economy. A small general equilibrium model is developed in which agricultural production takes place in two environments characterized by fixed land resources, and which accordingly experience differential rates of technical progress even while facing the same prices for output and variable inputs. The analytical structure permits not only the rate but also the factor biases of technical change to differ between environments. Distributional results are generated for several classes of households distinguished by their ownership of factors and by their patterns of consumption.

The analysis distinguishes between internationally traded goods (tradables), whose prices are determined in world markets, and nontraded goods (nontradables), whose prices are estab-

The authors are, respectively, an assistant professor, Department of Agricultural Economics, University of Wisconsin, and John Crawford Professor of Agricultural Economics, Research School of Pacific Studies, Australian National University.

The paper has benefitted from the helpful comments of two anonymous *Journal* referees.

lished entirely in domestic markets. Neutral technical change in a sector producing tradables has effects equivalent to those of an exogenous rise in its output price. Subsequent changes in endogenous factor and commodity prices can be divided into those resulting from the movements of domestic resources required to restore equilibrium in factor markets at a given level of consumer spending, called the resource movement effect, and those resulting from the increase in consumer spending made possible by technical progress, the spending effect (Corden and Neary).

The extent of relative factor price changes, and therefore of changes in the functional income distribution, is determined by the parameters governing factor demand and supply in each sector. Changes in the relative incomes of households (the owners of factors) are determined by the distribution of factor ownership and by the composition of household consumption bundles.

Two important results emerge from the analysis. The first is that following a technical change "shock," general equilibrium feedback from nonagricultural sectors of the economy will produce changes in income distribution. Such changes are not captured in partial equilibrium models of the agricultural sector on its own. The second is that the assumption, common to many general equilibrium models, that technical change is neutral with respect to factors potentially conceals its redistributive effects among groups of households with unequal endowments of land, labor, and other productive assets.

An illustration with Philippine data provides a convenient vehicle for discussion of these results. The parameters of this numerical form of the model are derived from the available empirical research on the Philippine economy. Nevertheless, the model is deliberately stylized and simplified so as to draw out the central analytical issues. Thus, the numerical simulations are intended primarily to serve this analytical purpose.

The Model and Solution Procedure

The model belongs to the Johansen class of general equilibrium models. All models of this type are linear in percentage changes of variables. This imbues them with great flexibility in the evaluation of comparative statics results from exogenous shocks. One advantage of particular relevance is that changes in variables deriving from two or more separate shocks are simply the

sums of changes due to individual shocks. In the simulations, this linearity property of the model is exploited to decompose changes in endogenous variables. The components of these changes comprise adjustments in individual factor and commodity markets in response to factor-neutral and factor-biased technical change shocks.

The model describes a small open economy in which three commodities are produced in four sectors. Two sectors (labeled 1 and 2) produce a single agricultural good, while sector 3 produces services, and sector 4 manufactures. Sector 3 output is the only product which is not traded internationally at given world prices. It is thus the only output price to be determined within the model. Each sector employs the mobile factors, labor and capital, and a specific factor. The specific factors in the agricultural sectors are endowments of land: irrigated land in sector 1 and unirrigated land in sector 2. The specific factors in services and manufacturing represent plant, buildings, and other "bolted down" capital.

The analytical structure is a generalized form of the model analyzed in Cassing and Warr. To capture the essence of the problem, the number of sectors has been increased from the three described by Cassing and Warr to the four defined above, and each sector is endowed with a specific factor. The higher dimensionality makes theoretical analysis of the model cumbersome and the focus, therefore, is on numerical simulations. Readers wishing a more detailed discussion of the analytical properties of this class of models may refer to Cassing and Warr.

The equations, variables, and parameters of the model are set out in tables 1 and 2. The equations fall into four groups. The first two describe, in turn, factor demand and product supply, and the supply of mobile factors. Firms employ factors from the aggregate pools of mobile labor and capital as well as using sector-specific factors, the supplies of which are exogenously determined. The third set of equations describes the activities of households as earners and as consumers. Each household contributes to the aggregate supply of factors and receives income commensurate with the returns on those assets. Household incomes are exhausted in the purchase of goods. The equations in this group describe, in turn, changes in household income, household-specific price indices, real household incomes (deflated by their price indices), household consumer demands, and aggregate consumer demand.

The fourth group of equations determines the prices of factors and of the nontradable com-

^a Prime superscripts indicate proportional changes. Thus $X' = dX/X$. Variable and parameter definitions are listed in table 2. Sectors are indexed by s , households by h . The subscripts l , k , and y denote labor, capital and output, respectively. Numerical subscripts refer to individual sectors.

modity. It comprises four sectoral zero pure profit conditions based on the assumption of constant returns to scale and three market-clearing conditions: one for the endogenously priced nontradable (services), and one for each of the domestically mobile, endogenously priced factors, labor and capital. These seven equations simultaneously determine changes in the model's seven endogenous prices: the price of services, the prices of labor and capital, and returns to the four specific factors.

The market-clearing conditions for final commodities require explanation. The model implies two market-clearing conditions for final commodities: one for the nontradable stating that changes in the demand for and supply of that commodity must be equal and one for tradables stating that changes in the value at international prices of exports must be matched by changes in the value of imports, implying that the level

of the trade deficit or surplus is held constant. Of course, there are two traded commodities, but only one market-clearing condition, the trade balance constraint, linking changes in the excess supply of one (exports) to changes in the excess demand for the other (imports). Walras' law now implies that provided the model's consumers operate on their budget constraints, one of the two market-clearing conditions is redundant. Either one implies the other. Following Cassing and Warr, it is convenient to retain the market-clearing condition for nontradables and to suppress the trade balance constraint.¹ This choice is purely a matter of convenience; retaining the trade balance constraint and suppressing the market-clearing condition for nontradables would have given exactly equivalent results.²

Because variables enter the model only in percentage change form, it is not necessary to specify their initial absolute magnitudes or to calibrate solution values by assigning a real-valued intercept to each equation. Only the relative magnitudes of variables are used, expressed as sectoral shares in GDP and factor demand, sectoral distributive shares of factors, and household shares in consumption and factor supply. Parameters of the equations describing factor demand and product supply are elasticities. For the two agricultural sectors, these are taken from the econometric estimates reported in Coxhead. All data are contained in a working paper available upon request from the authors.

Technical Change

Three hypothetical forms of technical change are simulated in the analysis: (a) factor neutral; (b) labor saving, capital using; and (c) labor using, land saving. The nature and magnitudes of these

¹ This specification of the general equilibrium system does not explicitly include the demand functions for the two tradable commodities. The reason is that the relevant parameters are implied in full by the demand function for nontradables and the assumptions of the model. This arises because: (a) the fixed relative prices for the two tradable commodities make them a single Hicksian composite good from the consumers' standpoint, and so, effectively, only two goods are consumed—the composite tradable and the nontradable; and (b) the usual assumptions that demand functions are homogenous of degree zero and that consumers satisfy their budget constraints exactly now enable all the usual elasticity properties of the demand function for tradables to be inferred directly from the demand function for nontradables, using the familiar aggregation conditions.

² Generalizing this discussion, if there are n tradables and m nontradables, there are $m + 1$ market-clearing conditions: one for each nontradable and a trade balance constraint. One is redundant. Any m of these equations determine the m -endogenous relative prices in the model.

Table 2. Variables and Parameters in the Model

Symbol	Definition	Number of Equations
Endogenous Variables		
L_s	Labor demand in sector s	(s)
K_s	Capital demand in sector s	(s)
Y_s	Product supply in sector s	(s)

β_{ij}^s	Elasticity of demand for factor i with respect to factor price j in sector s	
β_{iy}^s	Elasticity of demand for factor i with respect to output price y in sector s	
β_{iz}^s	Elasticity of demand for factor i with respect to fixed factor z in sector s	
β_{yi}^s	Elasticity of supply of good y with respect to factor price i in sector s	
β_{yy}^s	Elasticity of supply of good y with respect to own price in sector s	
β_{yz}^s	Elasticity of supply of good y with respect to specific factor z in sector s	
λ_{is}	Employment share of factor i in sector s	
ε_{hi}	Own-price elasticity of supply of factor i from household group h	
ε_i	Aggregate own-price supply elasticity of factor i	
δ_{hi}	Share of income of household group h derived from earnings of mobile factor i	
γ_{hs}	Share of income of household group h derived from earnings of specific factor Z_s	
μ_{h3}	Expenditure share of household group h on good 3	
η_{h3}	Expenditure elasticity of demand for good 3 by household group h	
ϕ_{hi}	Share of household group h in ownership of factor i	
ψ_{h3}	Share of household group h in consumer demand for good 3	
ξ_{h3}	Price elasticity of demand for good 3 by household group h	

^a For definitions, see text.

shocks are illustrative of individual technical innovations in developing country agriculture. Each type of shock, or any combination, may be applied either uniformly in both agricultural sectors or to only one of the two. This property permits examination of the differences in actual and potential productivity between irrigated and other agricultural areas.

Technical change alters product supply and factor demand directly in the sector to which the shock applies and indirectly in all sectors through adjustments in factor and product markets. The values of these changes are obtained by the requirement that changes in supply equal changes in demand in the markets for labor, capital, and the nontradable good. Because the model is oriented to the short run, changes in mobile factor supplies are constrained to zero; thus, any change in the functional distribution of income can be read directly from changes in factor prices.

The technical change specification in the model is adapted from Quizon and Binswanger (1983). In their analysis the rate and the bias of technical change in sector s can be obtained from the values of the factoral rates of technical change, A'_{is} , for each factor i . The A'_{is} terms are the percentage changes in factor demand due to technical progress, evaluated at constant prices and output:

$$A'_{is} = \frac{\partial X_{is}}{\partial t} \frac{1}{X_{is}},$$

where X_{is} denotes the demand for factor i in sector s , and t denotes time. The overall rate of technical change T'_s is the cost-share-weighted average of the A'_{is} terms:

$$T'_s = \sum_{i=1}^n \alpha_{is} A'_{is},$$

where α_{is} denotes the share of factor i in total costs in sector s . For ease of exposition, in the subsequent discussion the sector subscripts will be suppressed.

A'_i and T' are defined when output is held constant, as is the case in a cost function. Quizon and Binswanger (1983) derive the following expressions for E'_i and E'_y , the profit function counterparts of A'_i and T' above:

$$(1) \quad E'_i = \beta_{iy} T' + A'_z - A'_i; \text{ and}$$

$$(2) \quad E'_y = \beta_{yy} T' + A'_z,$$

where β_{ij} is the elasticity of quantity i with respect to the price of j , and A'_z is the factoral rate of technical change of land, the fixed factor in

the profit function. In this model the E'_i 's and E'_y in the agriculture sector supply and factor demand equations are replaced by the right-hand sides of equations (1) and (2). Selecting values of the A'_i 's and T' permits the simulation of any combination of technical change rates and biases, as will now be shown.

Factor-neutral technical progress in any sector is characterized by equality of each of the factoral rates of technical change A'_i and the overall rate of technical change T' . This equality implies the following changes in factor demand and output in that sector:

$$(3) \quad \begin{aligned} E'_l &= \beta_{ly} T' \geq 0; \\ E'_k &= \beta_{ky} T' \geq 0; \text{ and} \\ E'_y &= (\beta_{yy} + 1) T' \geq 0. \end{aligned}$$

Technical progress which substitutes capital for labor with no change in output or in the productivity of land ($A'_z = T' = 0$) yields

$$(4) \quad \begin{aligned} E'_l &= -A'_l \leq 0; \\ E'_k &= \left(\frac{\alpha_l}{\alpha_k} \right) A'_l \geq 0; \text{ and} \\ E'_y &= 0. \end{aligned}$$

These expressions show that the *ceteris paribus* effect of the capital-using bias of technical change is to reduce labor demand and raise capital demand. Reversal of k and l subscripts will yield expressions for the effects of a capital-saving, labor-using bias.

The third illustrative technical change involves the substitution of labor for land, with no change in the rate of technical progress or in its bias with respect to capital ($A'_k = T' = 0$). Because land is a specific factor and constant returns to scale have been imposed, at constant prices any increase in land productivity automatically ensures an increase in output even though the physical land area remains unchanged. In this case the technical change shifters are

$$(5) \quad \begin{aligned} E'_l &= \left(\frac{\alpha_z}{\alpha_l} + 1 \right) A'_z \geq 0; \\ E'_k &= A'_z \geq 0; \text{ and} \\ E'_y &= A'_z \geq 0. \end{aligned}$$

According to these definitions, the individual components of any technical change which both increases output and alters factor proportions can be isolated by applying shocks to individual

variables: T' for factor neutrality, A'_i for labor-capital bias, and A'_l for land-saving, labor-using bias. The nonneutral changes (4) and (5) impart only pure factor substitution effects; but, since the model is linear in percentage changes, either or both may be combined with the results for neutral change to simulate the effects of progress which both raises output and alters the proportions in which factors are demanded at constant prices. Any combination of technical progress and factor bias can be represented in the manner just described so long as the number of technical change variables (T' and the A'_i terms) in each sector is equal to the number of factors employed in that sector.

The effects of other combinations of factor bias and output increase could readily be specified; for the illustrative purpose served by this model, however, the three just described are adequate. In the experiments simulating unbalanced growth in agriculture, technical changes in sector 1 only are described, but an equivalent methodology applies to sector 2 because technical change mechanisms are algebraically identical in both sectors. The effects of a constant rate and bias of technical progress across both agricultural sectors are also presented and discussed below.

Household Income and Consumption

The model contains seven illustrative groups of households, distinguished both by asset ownership and by their consumption behavior. They are summarized in table 3. The small farmer categories (H6 and H7) include tenant farmers on fixed-rent leases because they also derive benefits from increased land productivity when output rises. The definitions of households used in this study have no direct equivalents in official Philippine statistics, in which households are grouped by levels of income and expenditure. Such information on consumption patterns as can be gleaned from official statistics (NEDA, various years) and independent studies (Pante; Lluch, Powell, and Williams; Kravis, Heston, and Summers) has been used to construct typical sets of consumer demand parameters for each of the household groups. Shares of total household income contributed by each factor owned by the k th household group are shown in table 4. These data have been constructed synthetically with the aim of providing a contrast between stereotypical groups.

The extent to which the incomes of farmers and landlords are derived from the earnings of

land reflects the assumption that they own or lease farm land in which they have made some long-term investment; for this reason their fortunes are closely tied to profitability in the sector in which their land belongs. The sector-specificity of farmers' incomes from land is not contradicted by their also deriving income from each of the mobile factors: their endowments of labor, for example, may be switched between on-farm and off-farm employment as changes in sectoral profitability dictate.

Laborers do not share in the ownership of fixed assets; their incomes are affected by a change in a particular sector only insofar as it affects the economy-wide demand for their services. Households owning specific factors outside agriculture, in services (H2) and manufacturing (H3), have asset ownership positions roughly equivalent to those of landlords: although they derive some income from their ownership of mobile capital, the greater portion comes from returns to specific factors. Changes in sectoral profitability are, thus, the main determinants of changes in these households' relative prosperity.

Solution Procedure

The model is implemented using the GEM-PACK software package (Codsí and Pearson).

Table 3. Household Categories and Characteristics

Code	Description	Asset Ownership
H1	Landless laborers	Mobile labor only
H2	Service sector capitalists	Specific factor in sector 3; some mobile capital
H3	Manufacturing sector capitalists	Specific factors in sector 4; some mobile capital
H4	Landlords in irrigated area (sector 1)	Most irrigated land, some mobile capital
H5	Landlords in unirrigated area (sector 2)	Most unirrigated land, some mobile capital
H6	Small farmers in irrigated area (sector 1)	Some irrigated land, some mobile labor and capital
H7	Small farmers in unirrig. area (sector 2)	Some unirrigated land, some mobile labor and capital

Note: Exact quantities of factors owned by each group are shown in table 4.

^a Household groups (defined in text) are *H1*, laborers; *H2*, owners of sector 3's specific factor; *H3*, owners of sector 4's specific factor; *H4*, landlords in sector 1; *H5*, landlords in sector 2; *H6*, farmers in sector 1; and *H7*, farmers in sector 2.

^b Figures in parentheses indicate ϕ_{hi} , the proportion of the economy's endowment of each factor *i* owned by household group *h*.

In table 1 the complete model is shown to consist of $(4s + 4h + 6)$ equations and $(5s + 4h + 17)$ variables. Because tradables' prices are assumed constant, their percentage changes are set to zero in the model's equations. Closure is achieved by specifying as exogenous the technical change shifters E'_i and E'_y and the endowments of capital, labor, and fixed factors \bar{K}' , \bar{L}' , and Z'_1 to Z'_4 . This leaves $(4s + 4h + 6) = 50$ endogenous variables and the same number of equations, permitting the model to be solved.

Sensitivity Analysis

Each of the parameters obtained by econometric analysis is estimated with error resulting from random variations in the data. Many other parameters of the model are derived not from econometric estimates but from independent information such as national accounts data. Considerable uncertainty over the values of these parameters is justified.

The possibility of errors in parameter values raises two issues. One is that the means by which some values have been obtained leaves open the possibility that they could be substantially different from their true values. The second is that the model may be extremely sensitive even to small changes in some parameter values. An empirical investigation of the second issue provides guidance as to the importance of the first. If the solution values of the model's dependent

variables are very insensitive to changes in parameter values, then uncertainty about the exact value of a parameter need not greatly reduce confidence in the outcomes of simulation experiments.

Sensitivity elasticity is defined as the percentage change in a solution value given a 1% change in the value of a parameter or parameter group (Pagan and Shannon, Anderson and Warr). Sensitivity elasticities were computed for each variable with respect to a 10% change in each parameter for a neutral technical change shock in sector 1. With 43 variables and 197 parameters in the model, 8,471 such elasticities could in principle have been calculated. The actual number computed was somewhat smaller (5,461) because it excluded changes in elasticities relating to changes in tradables' prices—these were held constant in our model—and parameters whose initial values were zero.

The solutions obtained for the base (neutral technical progress) simulation run are relatively insensitive to large changes in both estimated and guesstimated parameter values. Of the 5,461 sensitivity elasticities computed, only 93 (1.7%) exceeded 1.0 in absolute value; among these, the modal value was less than 2.0. These results indicate that the model is relatively robust with respect to its parameters.³

³ More detail on the procedure and results for sensitivity analysis is available from the authors on request.

Experimental Results

In this section we report and discuss the results of technical progress shocks conducted under a variety of assumptions concerning sectoral access to new technologies and factor biases. The purpose of these experiments is to expose the mechanisms by which functional and household income distributions are altered by a shock. First, counterfactual factor-neutral shocks are decomposed into their economic components. Second, the impacts of factor biases in technical change are studied in isolation from one another using hypothetical values of the technical change parameters T' , A'_i and A'_j . Although the data used in the model are based on Philippine data, the underlying model is, by design, highly stylized.⁴

The results are presented below by decomposing the percentage change in each endogenous variable into two components: the resource movement effect and the spending effect. The resource movement effect describes changes due to adjustments other than the spending of additional income generated by technical progress. Since the spending effect operates through demand for the non-tradable good (Corden and Neary; Cassing and Warr) the resource movement effect is calculated in these simulations by setting the expenditure elasticity of demand for the non-tradable, η_3 , equal to zero, which nullifies the spending effect. The resource movement effect is further divided into the factor market effect and the real appreciation effect.⁵ The former is calculated by holding the *numéraire* price of the nontradable constant, which nullifies the real appreciation effect. The log-linearity of the model ensures that the effects of an exogenous shock can always be represented as the sum of these components. In this manner the analysis exposes the relative importance of factor market and consumption linkages, and of the agriculture/nonagriculture terms of trade, in determining the distributional outcomes of technical change shocks. By revealing the major adjustment mechanisms, decomposed results reduce substantially the "black box" nature of CGE experiments, thus helping nontechnical users of such

models to gain an intuitive understanding of the results obtained.

The absolute prices of the two internationally traded commodities, the agricultural good and the manufactured good, are held constant throughout the analysis. Other prices, all of which may change relative to those of these *numéraire* goods, are measured in terms of the *numéraire* goods, and are thus called *numéraire* prices.

Balanced Technical Progress

An intuitive grasp of the results is made easiest by first considering the case in which a uniform, factor-neutral technical change occurs in sectors 1 and 2 together. Percentage changes in selected endogenous variables resulting from a uniform 10% increase in the productivity of all factors in agriculture are reported in columns (1) to (5) of table 5. For prices, the real changes reported are obtained by dividing changes in *numéraire* prices by the GDP-share-weighted sum of changes in commodity prices. These will be called changes in deflated prices.

In the balanced technical change case, sectors 1 and 2 have equal access to new technology. Output and factor demands rise in both sectors as the result of technical progress. Because producers in sector 1 (irrigated agriculture) are more price responsive than their counterparts in sector 2 (unirrigated agriculture) (Coxhead), output and associated factor demands rise by somewhat more in the former than in the latter. At constant output prices (column 1), the additional factor demand in agriculture is met by drawing capital and labor out of services and manufacturing. Real prices of the mobile factors rise accordingly, with the greater increase accruing to labor, because that is the mobile factor used relatively intensively in agriculture. Real returns to fixed factors in the expanding agricultural sectors rise by more than the amount of the technical change (as predicted for lower-dimensional models by Jones), while returns to fixed factors in other sectors fall as increases in mobile factor prices reduce profitability. At constant output prices, the technical change shock raises the incomes of the owners of factors used relatively intensively in agriculture, labor and land, with the greatest share of the increases captured by owners of the factors in least elastic supply. Thus, among the households, the greatest real gains are won by landlords, with lesser gains to farmers (who own some land, labor, and capital),

⁴ A 42-sector general equilibrium model of the Philippine economy is presently under construction by the authors.

⁵ A real appreciation is a rise in the price of nontradables relative to the prices of tradable commodities, i.e., a rise in the real exchange rate. The real appreciation effect as defined here refers to the *ceteris paribus* effect of a rise in the relative price of nontradables, net of the effects of factor market adjustments and income effects.

Table 5. Effects of Neutral Technical Change Shocks in Agriculture (%)

Endogenous Variable	Balanced Growth ($T'_1 = T'_2 = 10.0$)					Unbalanced Growth ($T'_1 = 10.0$) Total Change (6)

Note: For full details of simulation results see Coxhead and Warr (1989).

and considerably lower gains accruing to laborers.

The second component of the resource movement effect is the real appreciation effect, shown in column 2 of the table. Relative to all commodity prices, the price of the nontradable rises by a little more than 1%. This rise in profitability in the nontradable sector draws mobile factors away from other sectors: the demand for capital and labor rises in sector 3 and falls in all other sectors. Output in the nontradables sector recovers about half of the ground lost from factor market adjustments: having fallen by 1.47%, the rise in P_3 reduces the decline in output to -0.45%. The deflated return to the specific factor in sector 3, which was cut by 3.57% by the factor market adjustments, rises as the result of real appreciation by 3.43%: the net impact of

the resource movement effect on the return to this factor is thus virtually zero. This result stands in contrast to that for the manufacturing sector. De-industrialization takes place both directly through the movement of factors into agriculture and indirectly through the real appreciation. Output in sector 4 falls by 2.11% as the result of the resource movement effect of the shock.

In real terms, the rise in nontradables' price resulting from the resource movement effect has no effect on wages or returns to mobile capital but raises the return to the factor specific to the nontradables sector. As the zero pure profit conditions require, the change in P_3 is "trapped between," i.e., is a factor share-weighted average of, changes in the prices of factors used in the production of nontradables.

Real changes in household income are ob-

tained by deflating *numéraire* incomes by household-specific commodity price indices. On its own, the real appreciation component of the resource movement effect redistributes some of the incremental income derived from the technical progress away from agriculturalists towards the owners of the factor specific to nontradables: the real incomes of households in the group *H3* rise. Laborers also gain. Rises in returns to their endowments of mobile capital are insufficient to offset the losses experienced by landlords and the owners of the specific factor in manufacturing.

The spending effect boosts output and factor demand in nontradables primarily at the expense of the manufacturing sector, although agricultural factor demands and output levels also fall slightly. Increased demand raises the real price of nontradables by 13.4%, considerably more than the rises in returns to mobile factors and more than ten times greater than the real appreciation associated with the resource movement effect. This contributes to a final outcome for deflated factor returns, which confirms a rise in wages (2.24%) about double that in returns to mobile capital (1.11%). A large rise in the return to the factor specific to nontradables from the spending effect yields an overall rise in that factor's real price of 44%. Real returns to manufacturing's specific factor fall by 33%. Of greatest interest is the impact of the spending effect on real returns to agricultural land: the gains from the technical change shock are virtually cancelled by subsequent changes in mobile factor prices and in the price of nontradables.

Unbalanced Technical Progress

In the developing countries of Asia, a disproportionately large part of public investment in agricultural research and extension has been directed toward the improvement of agricultural productivity in irrigated areas. The rate of technical progress in these areas has consequently been much greater than that in areas without access to irrigation (David and Otsuka). The changes in prices and incomes resulting from a technical change shock restricted to one agricultural region (sector 1) are shown in column 6 of table 5. Most of the additional income generated directly by the technical progress is captured by landowners in sector 1, especially by landlords. As in the balanced growth case, the spending effect substantially increases profitability in the nontradable sector. In sector 2, ris-

ing factor prices reduce profitability, driving down output and the rents paid to sector-specific land. The real appreciation, the indirect component of the resource movement effect, appears to all agricultural producers as a fall in the price of their output relative to the general commodity price level. Without the opportunities for unit cost reductions provided by the new technologies, this further reduces profits and output in the lagging agricultural sector. Moreover, the operation of the spending effect on the demand for nontradables spurs further factor price rises and another reduction in the relative price of farm produce, and so further reduces profits in sector 2. These losses inflicted on the lagging agricultural sector by its lack of access to new technologies are not captured by most empirical partial equilibrium analyses.

Unbalanced Growth and the Distribution of Income

The functional income distribution. The changes in real factor returns shown in table 5 enable us directly to compare changes in real income between the owners of sector-specific land endowments in the two agricultural sectors. A second comparison of interest in developing countries is between the income of labor and the aggregate return to land. Because labor is mobile between sectors, it is appropriate to compare the change in its income with the change in income accruing to all agricultural land, rather than to land in a single sector. Changes in the aggregate return to land are calculated as the weighted average of changes in land prices in sectors 1 and 2, calculated from columns 5 and 6 of table 5. The weight used is θ , the value of production in irrigated areas as a proportion of the total value of agricultural production. In 1980, the reference period of the Philippine data used in simulations, the value of θ was 0.2087.

When both agricultural sectors grow, the difference between sectors 1 and 2 in the changes in real returns to land is negligible. The θ -weighted average of these changes, the percentage change in the aggregate return to land, is calculated as

$$z'_{agg} = \theta(0.70) + (1 - \theta)(0.67) = 0.68.$$

Under unbalanced growth the gap is naturally much wider, composed not only of an increase in the real return to land in sector 1 but also of a fall in the real return to land in sector 2. Consequently, if growth is unbalanced the change

in aggregate returns to land is actually negative:

$$z'_{agg} = \theta(12.31) + (1 - \theta)(-10.05) = -5.38.$$

These results are summarized in column 1, rows 1 and 2, of table 6. The second column of the table shows that when the rate of technical progress is uniform in both sectors, owners of land lose slightly relative to laborers. At 1.56%, the difference between changes in land and labor returns is small enough for the effect of balanced growth to be described as neutral with respect to the labor-land distribution of income. When technical progress occurs only in sector 1, however, labor gains relative to landowners: subtracting the aggregate landowners' loss from the 1.33% rise in labor income yields a margin of 6.71%.

The mobility of labor, combined with the fact that labor gains from both the factor and product price components of the resource movement effect as well as from the spending effect, ensures that among factors employed in agriculture, labor captures a substantial share of the total gains from the factor-neutral technical progress. Whether or not labor gains relative to capital depends on the relative factor intensities of the sector experiencing technical progress and of the sector producing nontradables, and on the rate at which each sector grows. Under balanced growth in the labor-intensive agricultural sectors, the increase in labor demand is much greater than that of capital; wages thus rise relative to capital's price. When only sector 1 experiences technical progress the relative wage rise is halved, to 0.53%.

Analyses of technical progress which consider only the distribution of gains among factors employed wholly within agriculture ignore the impact of the spending effect on factor price relativities. That this omission can result in completely different interpretations of the dis-

tribution of factor incomes following technical progress is evident from rows 3 and 4 of table 6, which show changes in relative factor prices resulting only from the resource movement, or direct effect, of the technical change shock. Column 2 of the table shows that on its own, the resource movement effect reduces wages relative to land rents by 16% if growth affects both agricultural sectors and by 2% if it is restricted to sector 1. In Quizon and Binswanger's (1986) model of agricultural growth in India, nonagricultural production and technology are by assumption exogenous, which implicitly requires that agricultural growth has no effect through backward or forward linkages on factor demand in other sectors. Their finding that technological improvements in agriculture do less to improve the incomes of India's rural poor than do increases in nonagricultural employment (Quizon and Binswanger 1986, p. 105) must be evaluated in the light of their assumption that labor markets are dualistic in structure.⁶

The household income distribution. The household distribution of income is found by mapping the functional distribution onto the pattern of asset ownership by which household groups are defined. Under balanced agricultural growth, landlords in sectors 1 and 2 experience similar rises in real income, as do the two small farmer groups (table 5, column 5). In the unbalanced growth case, sector 2's landlords and farmers lose in real income because of the fall in returns to their land (column 6). As with factor returns, it is relevant to contrast the house-

⁶ Among the strongest backward and forward linkages of agriculture in developing countries are those to rural-based, labor-intensive activities with a high nontradables component. These include grain milling, food processing, transport and storage, input supply and small-scale implement manufacture and supply.

Table 6. Comparative Changes in Factor Returns from Neutral Technical Progress (%)

	Land Price Ratio ($z'_1 - z'_2$) (1)	Wages Relative to Aggregate Land Price ($w' - z'_{agg}$) (2)	Wages Relative to Capital Price ($w' - r'$) (3)
Total effect of technical change shock			
Balanced growth	0.03	1.56	1.13
Unbalanced growth	22.34	6.71	0.53
Resource movement effect only of technical change shock			
Balanced growth	4.09	-15.98	0.81
Unbalanced growth	24.57	-2.04	0.38

hold income changes experienced by laborers against those of landlords and farmers in sectors 1 and 2 together. The change in the real income of equivalent groups in both agricultural sectors is computed as the θ -weighted sum of changes in real income of each household group. These comparisons are shown in table 7.

In the balanced technical progress experiment real returns to land, labor, and capital all rise.⁷ Table 7 shows that farmer households, whose endowment bundles include some of each factor, gain income relative to laborers and also relative to landlords, who own land and mobile capital. Landlords lose income relative to laborers. When technical progress is restricted to sector 1, however, the gains of laborers relative to both farmers and landlords are positive, even though they lose relative to landlords and farmers in sector 1, because of the losses incurred by landlords and farmers in sector 2.

Income distribution between households owning factors employed in agriculture appears quite

stable when rates of (neutral) technical progress are equal in both agricultural sectors. The relative gains of landowners from the resource movement effect are offset by gains accruing to owners of mobile factors when the spending effect is taken into account. Under unbalanced growth, disparities in income changes within each sector are greater; for example, laborers lose substantially relative to landlords in sector 1. This is so primarily because the spending effect, and consequent increases in labor demand and reductions in the real price of agricultural output, is much smaller relative to the balanced growth case.

These distributional results illustrate an important feature of the general equilibrium approach to the distribution of gains from technical progress. Partial equilibrium models and some "limited" general equilibrium models (Quizon and Binswanger 1986) attempt to capture the effects of changes in relative prices by assuming that the demand for agricultural output is price inelastic. This approach fails to take account of the effects on nonagricultural production and factor demand resulting from changes in the prices of intersectorally mobile factors. The true general equilibrium impact of technical change is thus captured only partially through commodity prices. The effects of changes in mobile factor prices are also important for the results in agriculture. By contrast with partial equilibrium approaches, in a properly specified general equilibrium model demand for the good produced in the sector experiencing technical progress need not be inelastic in order for the greater part of the gains from growth to be captured by groups other than owners of factors specific to that sector. It is sufficient that the mobile factors used in the expanding sector are also used to produce another commodity (in this

⁷ In table 5, column (5), the real prices of both mobile factors are seen to rise following a factor-neutral technical change shock. This harmony of the interests of labor and capital contrasts with the conflict implicit in models with fewer specific factors (see Cassing, and Warr, and Corden and Neary). We can summarize the preconditions for such a result. If factor supply elasticities are equal, then for the change in the wage-rental ratio $w'-r'$ to be unambiguously positive (negative) requires that both the sector experiencing technical progress and the sector producing nontradables, which grows as a result of the spending effect, be labor-intensive (capital-intensive) in terms of the two mobile factors. In this simulation model sector 1, the so-called "booming" sector, is labor intensive relative to capital. The resource movement effect of the technical progress thus raises $w'-r'$. Sector 3, however, is capital intensive relative to labor, so the spending effect lowers $w'-r'$. When the general equilibrium effects of the technical progress "boom" are taken into account, the interests of owners of the mobile factors are not opposed. Rather, their combined interests are in opposition to those of the owners of specific factors because any rise in specific factor endowments raises w and r relative to all specific factor prices and vice versa.

Table 7. Comparative Changes in Real Household Incomes from Neutral Technical Progress (%)

Income Gains of:	Relative to:	Balanced Growth	Asymmetric Growth
Laborers (H1)	Landlords 1 (H4)	4.77	-3.47
Laborers	Landlords 2 (H5)	4.83	8.79
Laborers	All landlords	4.82	6.23
Laborers	Farmers 1 (H6)	-0.22	-3.66
Laborers	Farmers 2 (H7)	-0.28	4.08
Laborers	All farmers	-0.27	2.47
Farmers 1	Landlords 1	4.99	0.19
Farmers 2	Landlords 2	5.11	4.71
All farmers	All landlords	5.09	3.76

case, nontradables) whose price is endogenous and responsive to changes in domestic demand. The inflation of this price caused by income effects arising from the technical progress and resulting factor market adjustments is sufficient to reduce the real price of the good produced in the expanding sector.

Biased Technical Change

Equations (4) describe the constant-price effects of a technical change which substitutes capital for labor with no increase in output.⁸ Column 2 of table 8 summarizes the total change in prices and incomes from both the resource movement and spending effects of such a shock. The substitution of capital for labor in sector 1 results in a real wage decline of 1.67%, in spite of the substitution of labor for capital in all other sectors. Sectors facing elastic demand for their output (1, 2, and 4) benefit from falling (deflated) wages, and their outputs rise slightly.⁹ Households owning only labor lose from the labor-saving change: their real incomes fall by 1.49%. Farmers in sector 2 also derive much of their income from labor, and, because they do not

benefit as landowners from technical progress in sector 1, their real incomes fall slightly. Households not dependent on labor experience small rises in real income. For sector 1 farmers, the gains from rises in land returns just offset losses in their labor incomes. Because laborers and small farmers comprise most of the low-income families in developing countries, a labor-saving, capital-using technical change bias must lead to a worsening income distribution.

In the second nonneutral component of technical progress considered in table 8, labor is substituted for land. Declining per capita availability of arable land in the Philippines has spurred the adoption of a range of technologies which economize on its use. Irrigation and high-yielding grain varieties rely on substantial increases in the per hectare inputs of both labor and intermediate goods. Column 3 of table 8 reports the total changes in prices and incomes following the labor-using, land-saving shock described by equations (5). Because both mobile factors are complementary with land and the effective land area has been increased by the shock, real wages as well as returns to mobile capital increase. Because the change is labor using, wages increase substantially relative to capital's price (the difference is 2.44%), and real returns to fixed factors are greatly reduced. Together, these results ensure a strongly positive effect on income distribution, given that laborers and small farmers are the poorest household groups in the economy. Laborers' real incomes rise by 5.38%, and those of small farmers in the lagging sector rise by 0.69%.

⁸ Recent Philippine examples of this type of change include the mechanization of land preparation (Sison, Herdt, and Duff; McCoy) and of rice threshing (Hayami and Kikuchi); and direct seeding, which is the substitution of herbicides for transplanting and weeding labor when the rice crop is established by broadcasting seed instead of transplanting (Moody and Cordova).

⁹ Full details of changes in factor demand and commodity supply are reported in Coxhead and Warr.

Table 8. Effects of Neutral and Nonneutral Technical Change Shocks in Sector 1

Endogenous Variable	Factor-Neutral ($T'_1 = 10.0$) (1)	Labor-Saving, Capital-Using ($A'_1 = 10.0$) (2)	Labor-Using, Land-Saving ($A'_2 = 10.0$) (3)

Fixed factor 4	-17.10	0.38	-10.25
Household incomes			
H1	4.01	-1.49	5.38
H2	16.52	2.70	-3.75
H3	-10.80	0.39	-6.28
H4	7.48	0.46	-2.25
H5	-4.78	0.57	-2.19
H6	7.67	-0.02	0.74
H7	-0.07	-0.13	0.69

Some of the qualitative effects of technical change are predicted by single-sector or partial equilibrium models. For example, virtually any such model will predict that land-saving, labor-using technical change in agriculture will produce a redistribution of income from landlords to laborers (e.g., Ahammed and Herdt). Other important effects, in particular those involving intersectoral linkages, will be missed by these models. A good example is the dramatic fall in returns to land in sector 2 resulting from the effect on factor prices of technical change in sector 1.

Empirically Estimated Technical Change Shocks

Values of technical change parameters appearing in the above model have been estimated from Philippine agricultural data (Coxhead). The estimates reveal a strong land-saving, fertilizer-using bias and fairly rapid overall rate of technical change in irrigated environments, and a much slower rate of technical change with correspondingly smaller biases in unirrigated environments. These values (shown in table 9, scaled to simulate an exogenous 10% technical change shock) were employed in additional experiments. The results, summarized in table 10, bear a close resemblance to the hypothetical effects of a neutral shock restricted to sector 1, as shown in column (6) of table 5. The spending effect, and the real appreciation component of the resource movement effect are less important in determining distributional outcomes than are the factor market adjustments associated with the shocks. Because the overall rate of technical progress in sector 2 is so low, real returns to owners of sector 2 land fall dramatically. Real mobile factor prices rise, with w' exceeding r' by 1.8%. The magnitude of the land-saving bias ensures that the real incomes even of sector 1

landlords fall relative to laborers' incomes. Laborers' incomes rise by 11.14% relative to aggregate landlords' incomes, and by 5.7% relative to all farmers' incomes.

Considered separately from contemporary changes in factor endowments and from changes in relative prices arising from other sources, the direction of technical change in Philippine agriculture appears to have brought relatively greater benefits to poorer groups (farmers and laborers), and thus to have exerted a positive influence on income distribution. This is so in spite of a clear worsening in the profitability of production in sector 2; the losses in that sector are absorbed by households owning sector 2-specific land in proportion to their ownership of it. Sector 2's landlords lose heavily, and the incomes of farmers in poor agricultural areas fall relative to those of laborers and of farmers in well-irrigated areas.

Conclusion

This paper has explored the short-run income distributional effects of technical change in agriculture with the aid of a small, stylized general equilibrium model. The model distinguishes between commodities which are traded internationally and those which are not, between fixed and mobile factors of production, and between technical changes of different factor biases. An important feature of the model is that it also distinguishes between groups of agricultural producers with and without access to resources complementary with the new technology, notably irrigation.

The simulations of the general equilibrium effects of technical change draw attention to the fact that the interests of owners of fixed factors do not necessarily coincide; returns to different fixed factors, or to the same fixed factor used in different sectors, may, and frequently do, move in different directions. It is well known that in

Table 9. Values of Empirical Technical Change Shocks

Sector	Land A'_L	Labor A'_L	Fertilizer A'_K	Overall Rate T'
Agriculture 1 (irrigated)	14.826	6.265	-1.911	7.645
Agriculture 2 (nonirrigated)	1.031	-1.164	-0.019	0.267

Source: Computed from estimates in Coxhead (1989).

Note: For factors $i = Z, L, K$, $A'_i > 0$ implies that at constant prices and output, technical progress has increased the productivity of (i.e., has "saved") factor i .

small open economies the interests of farmers are hurt by increases in manufacturing protection, so to find that technical progress in agriculture may injure producers elsewhere is not surprising. In the case of landowners in agricultural sectors not experiencing technical change, their losses as a result of technical progress elsewhere will prompt efforts to adopt similar technological innovations for their own farms, as has been pointed out by Quizon and Binswanger (1983). In practice, however, their gains from adoption are constrained by the lack of complementary inputs such as irrigation. In the Philippines, the adoption rate of modern rice varieties in rainfed lowland and upland areas is the highest in Asia. In spite of this, rainfed rice yields have grown only very slowly.

The results of this study point to three critical issues in determining the income distributional effects of technical progress. These are the price-setting mechanisms for intersectorally mobile factors, heterogeneity in the quality of sector-specific factors (in this paper, land), and the factor biases of technical progress. These three matters are precisely those in which the desire for simplicity in modeling and the weakness of the empirical base often lead researchers to make default assumptions. Factor prices are assumed either to be fixed, or to be determined wholly within the sector under study. Agricultural land is taken to be of homogenous quality, and technical change is taken to be neutral with respect to factors. The policy relevance of analyses of

the welfare and distributional impact of technical progress or equivalent changes would be enhanced by increased attention to these important issues.

Modeling Agricultural Growth Multipliers

Steven Haggblade, Jeffrey Hammer, and Peter Hazell

Agriculture's potential as an engine of third world growth depends, in large part, on the size of the production and consumption linkages it stimulates in rural regions. Current estimates of agricultural growth multipliers within rural regions vary widely, not only because economic structures differ across regions but also because the array of fixed-price models most commonly used embody widely differing basic assumptions. Among fixed-price models, the semi-input-output formulation projects the most plausible multipliers. But even they overstate the magnitude of growth multipliers by 10% to 25% according to the price-endogenous model developed here.

Key words: agricultural development, growth, multipliers.

Studies of the indirect consequences of the green revolution place regional agricultural income multipliers anywhere between 1.3 and 4.3. That is, a one dollar increase in technologically induced agricultural income generates an additional \$0.30 to \$3.30 in other sectors of a rural region (Ahmed and Herdt; Bell, Hazell, and Slade; Haggblade, Hazell, and Brown; Krishna; Little and Doeksen; Mirakhor and Orazem; Haggblade and Hazell). Although variations in economic structure across regions explain part of this wide range, differences in models and their assumptions may account for a greater share of the discrepancy.

And the magnitudes matter. Debate over agriculture's potential as an engine of third world growth hinges on the magnitude of the production and consumption linkages it generates (Hirschmann, Johnston and Kilby, Mellor). The linkages also play a central role in evaluating the equity implications of agriculture-led growth (Mellor and Johnston). In addition to their considerable dispersion, existing multiplier estimates may be overoptimistic. The models used to date—input-output, economic base and semi-input-output models—compute Keynesian demand-driven multipliers. All assume a perfectly elastic supply of nontradables. But if nontradable supply is not perfectly elastic, shifts in de-

mand will lead to higher prices and a reduction in estimated quantity increases (fig. 1). A price-endogenous model is required to capture these price effects and the resulting dampening of growth multipliers.

This paper aims to help quantify more precisely the magnitude of agricultural growth multipliers. It does so in two ways. First, the paper reviews the array of fixed-price models presently in use. It explores how they are related and examines analytically why they produce different multiplier estimates, even for identical economies. Second, it introduces a price-endogenous model that relaxes two key simplifying assumptions of the current fixed-price models: (a) it accommodates an upward-sloping supply curve for nontradables, and (b) it allows for substitution among inputs rather than insisting on fixed-coefficient Leontief production technology. The price endogenous model is then used to estimate the dampening effect of an upward-sloping supply of nontradables and to examine the consequences of input substitution for agricultural growth multipliers. To facilitate comparison, the paper applies the full complement of fixed-price and price-endogenous models to three specific rural regions to illustrate how differences in model assumptions affect multiplier estimates.

Steven Haggblade is an economist attached to Bojida Associates and is based in Dhaka, Bangladesh. Jeffrey Hammer and Peter Hazell are economists with the World Bank.

Fixed-Price Models

Most multipliers to date have been estimated using fixed-price models: economic base (EB), in-

put-output (I-O) and semi-input-output (S-I-O) models. To compute these multipliers, fixed-price models classify economic activities as tradable (T) or nontradable (N) according to the region's trade possibilities with the larger national economy and the rest of the world. For rural regions in developing countries, agricultural food grains or cash crops usually constitute the major tradable commodity, while nontradables usually include perishable agricultural goods such as fruits and meats, rural nonfarm services, and many rural manufactured goods.

All fixed-price models share three common assumptions. First, they view increased production of tradable goods as the driving force in regional economic growth. Second, they each model production as fixed-coefficient Leontief technology. And, third, they assume constant prices for both tradable and nontradable output.

To justify the constant output price for nontradables, practitioners invoke the supply-side assumptions of fixed technical coefficients, perfectly elastic supplies of inputs and consequently of output. These assumptions may be reasonable in regions where excess capacity and seasonality of labor demand in agriculture allow a highly elastic supply response much of the year. But, where labor supply is tight or short-run capacity constrains, the fixed-price assumption for nontradables becomes more tenuous. For tradables, on the other hand, modelers defend fixed prices on the grounds that they are modeling small, open, regional economies which face a constant, externally determined export price.

The major distinction among fixed-price models lies in their assessment of what constrains tradable output. While the input-output model portrays tradable output as demand-constrained, the semi-input-output and economic base models maintain that tradable output is limited by rigidities on the supply side; that is, by available resources and technology which limit output.

Rather than following the chronological order of their development, from EB to I-O to S-I-O, the following discussion begins with the semi-input-output model. It serves as the reference standard because, within the limitations of fixed-price models, we believe it most closely approximates the reality of third world agriculture. Its supply-constrained view of farm output accords with the frequent technological, land, or water constraints experienced in most developing country agriculture. By comparison, the input-output view that farmers can increase output in unlimited amounts at constant cost strains

credulity in a world where so many go hungry. Consequently, we begin with the most realistic, the semi-input-output model, and then show how the others are variants or special cases of it.

Although the S-I-O and I-O models allow unlimited disaggregation of tradable and nontradable activities, such disaggregation merely adds to the numerical precision of the estimated multipliers rather than to any conceptual understanding.¹ The following description, therefore, proceeds using a two-sector framework, because this greatly simplifies the exposition.

Semi-Input-Output Models (S-I-O)

(i) *Full two-sector S-I-O.* The semi-input-output model developed by Bell and Hazell describes a rural economy in which regional gross output of tradable commodities (T) is fixed by resource or technology constraints at \bar{T} . As in all fixed price models, the S-I-O assumes that nontradable output (N) is perfectly elastic. Its output level is, therefore, determined by local demand. Demand includes household consumption demand for nontradables (H_n), regional producer's intermediate demands for nontradables (D_n), government expenditure on nontradables (G_n), and regional investment demand for nontradables (J_n). Equations (1) through (6) spell out these basic relationships more fully.

- (1) $T = \bar{T}$ tradable output,
- (2) $N = H_n + D_n + \bar{G}_n + \bar{J}_n$ nontradable output,
- (3) $H_n = \gamma_n + \beta_n(Y - L)$ household consumption demand for N ,
- (4) $D_n = a_{nt}\bar{T} + a_{nn}N$ intermediate demand for N ,
- (5) $L = sY$ income leakages,
- (6) $Y = v_nN + v_t\bar{T}$ income definition.

Household consumption expenditure on nontradables increases linearly with income (Y) and depends on the rate of income leakage (L) to savings and taxes, the marginal share of total expenditure directed to nontradables (β_n), and a consumption function intercept (γ_n). Leakages are assumed a constant proportion (s) of total income. Assuming Leontief technology, inter-

¹ The economic base model, on the other hand, does not accommodate disaggregation beyond two sectors.

mediate demand for nontradables remains a constant proportion (a_{ij}) of sectoral gross output, where a_{ij} denotes intermediate deliveries from sector i to sector j . The model further assumes that government and investment expenditures are exogenous at $G_n = \bar{G}_n$ and $J_n = \bar{J}_n$. Finally, the model defines household income (Y) as a constant share of gross output (v_j) in each sector, where $j = T, N$.

Because the model imposes no balance of payments constraint, there is no need to keep track of regional tradable consumption by households or firms. As local consumption varies, exports adjust to equate regional supply and demand, and the model's solution is not affected.

Collecting terms in equations (1) through (6), the model can be written in matrix form, as

$$(7) \quad \begin{bmatrix} 1 - a_{nn} - \beta_n(1-s) \\ -v_n & 1 \end{bmatrix} \begin{bmatrix} N \\ Y \end{bmatrix} = \begin{bmatrix} K_n + a_{nt}\bar{T} \\ v_t\bar{T} \end{bmatrix},$$

where $K_n = \gamma_n + \bar{G}_n + \bar{J}_n$. The region's income depends on \bar{T} and the model parameters, as the solution to (7) indicates:

$$(8) \quad Y = \frac{[(1 - a_{nn})v_t + a_{nt}v_n]\bar{T} + v_nK_n}{1 - a_{nn} - \beta_nv_n(1-s)}.$$

Suppose that investment or technological change in agriculture enables the region to increase its output of tradables. What will be the multiplier impact on the region's income? The answer depends on how the new technology or investment affects the production function for tradables. At a general level, a_{nt} , v_t , and \bar{T} can all be postulated to be functions of θ , a technology shift parameter. In this case, $\partial(\bar{T}v_t)/\partial\theta$ measures the initial change in income in tradables production, and $dY/d\theta$ measures the change in regional total income as a result of the change in technology. The conventional value-added multiplier, which measures the increase in regional value added given a one-unit increase in value added from tradable output, is then obtained from (8), as

$$(9) \quad M = \frac{dY/d\theta}{\partial(\bar{T}v_t)/\partial\theta} = \frac{[(1 - a_{nn})\partial v_t/\partial\theta + v_n\partial a_{nt}/\partial\theta]\bar{T} + [(1 - a_{nn})v_t + a_{nt}v_n]\partial\bar{T}/\partial\theta}{[1 - a_{nn} - \beta_nv_n(1-s)][v_t\partial\bar{T}/\partial\theta + \bar{T}\partial v_t/\partial\theta]}.$$

A much simpler case arises if increases in tradable output do not change the use of inter-

mediate inputs per unit of output. Investments that simply overcome fixed factor constraints could have this effect; examples are land reclamation or additional irrigation in the absence of improved crop varieties. Under these conditions, $\partial v_t/\partial\theta$ and $\partial a_{nt}/\partial\theta$ equal zero, and (9) reduces to

$$(10) \quad M = \frac{1 - a_{nn} + a_{nt}(v_n/v_t)}{1 - a_{nn} - \beta_nv_n(1-s)} = \frac{1}{v_t} \cdot \frac{dY}{d\bar{T}}.$$

To simplify the presentation, we shall consistently adhere to this more restricted type of technological change. This is also consistent with many applied studies that use S-I-O, EB, or I-O models. However, it should be clear that all the models presented can readily be expanded to accommodate more general forms of technological change.

The multiplier captures the combined effects of interindustry linkages and the households' final demand linkages. To separate the two, it is only necessary to solve a variant of the model in which β_n is set equal to zero. Household consumption expenditure then becomes constant and the derived multiplier will be due entirely to production linkages. Modifying (10) in this way and simplifying, the production multiplier (M_p) becomes

$$(11) \quad M_p = \frac{1 - a_{nn} + a_{nt}(v_n/v_t)}{1 - a_{nn}}.$$

(ii) *Hazell's simplified S-I-O.* Hazell has developed a simplified version of the S-I-O model by assuming $a_{nn} = a_{nt} = a_n$ and $v_n = v_t = v$. These assumptions, not unreasonable for many developing country regions, reduce the S-I-O parameter requirements from 6 to 4.² The multiplier in this case becomes

$$(12) \quad M = \frac{1}{1 - a_n - \beta_nv(1-s)},$$

² It reduces the required parameters to three if, as in Hazell's original formulation, the leakage ratio (s) is ignored as well.

while the production linkages alone are

$$(13) \quad M_p = \frac{1}{1 - a_n}.$$

The Economic Base Model (EB)

The economic base (EB) model reduces data requirements still further. It estimates growth multipliers from a single parameter. Because of its extreme simplicity, the EB model has long proven popular, especially among practitioners in urban economics and in regional science (Richardson).

The model refers to a region's tradable sector as its economic base, the output of which, as in the S-I-O model, is constrained at \bar{T} .³ As with all fixed-price models, the economic base (EB) model assumes that nontradable output is perfectly elastic and determined solely by local demand.

The economic base multiplier can be derived in two ways. The first derivation, although less common, highlights the connection between the EB and other fixed-price models. It begins with the income equation in (6) and assumes that nontradable income, $v_n N$, remains a fixed share of total income, Y , that is,

$$(14) \quad v_n N = cY.$$

Total income then becomes

$$Y = v_t \bar{T} + v_n N = v_t \bar{T} + cY = v_t \bar{T} / (1 - c)$$

with a value added multiplier of

$$(15) \quad M = \frac{1}{v_t} \frac{dY}{d\bar{T}} = \frac{1}{1 - c}.$$

When compared to its S-I-O counterparts (10) and (12), it becomes clear that the economic base multiplier is formally identical to the S-I-O. It is a special case of Hazell's S-I-O multiplier arising when

$$(16) \quad c = a_n + \beta_n v (1 - s).$$

Because its single parameter, c , incorporates both

household's final demand and business purchases of intermediates, the economic base model, unlike the S-I-O and I-O models, cannot be used to separate out production from consumption linkages.

A second, more common, derivation of the EB model leads directly to the operational formula preferred by practitioners. From (14) it follows that tradable income $v_t \bar{T}$ is also a fixed share of total income. Its share is $(1 - c)Y$. The ratio (k) of nontradable to tradable income is, therefore,

$$(17) \quad k = v_n N / v_t \bar{T} = c / (1 - c).$$

Thus, the multiplier in (15) is equivalent to

$$(18) \quad M = 1 + k.$$

Practitioners find this version of the multiplier attractive because of its effortless computation once the income data are obtained.

Input-Output Models (I-O)

A closed I-O model with household demand endogenous differs from the S-I-O model in only one respect. It assumes the output of tradables is perfectly elastic and is constrained by export demand alone. Thus, instead of $T = \bar{T}$, the output of tradables is given by

$$(19) \quad T = H_t + D_t + \bar{G}_t + \bar{J}_t + \bar{E}_t,$$

where \bar{E}_t denotes the fixed level of exports. Following an initial spurt in tradable output, the model permits T to increase still further in successive rounds through increased household (H_t) and intermediate demand (D_t), even though \bar{E}_t remains fixed. Because this additional source of growth in regional demand cannot occur in the S-I-O and EB models, the closed I-O model leads inevitably to the largest multipliers.

Defining household (H_t) and intermediate demand (D_t) for tradables analogously to nontradables demand (2) and (4) results in relationships of the following form:

$$(20) \quad H_t = \gamma_t + \beta_t (Y - L)$$

$$(21) \quad D_t = a_n T + a_m N.$$

After combining (19)–(21) and their nontradable counterparts (2)–(4) with the regional income definition (6), the closed I-O model can be written in matrix notation as

³ North, Tiebout, and many others assert that T is constrained by export demand. But this explanation is not consistent with the workings of the model because the model precludes second-round, demand-driven increases in T as a result of an initial increase in its own output. So, in spite of assertions to the contrary, the EB models are formally identical to the S-I-O, and both are founded on the assumption of supply-constrained tradable output.

$$(22) \quad \begin{bmatrix} 1 - a_{nn} & -a_{nt} & -\beta_n(1-s) \\ -a_{tn} & 1 - a_{tt} & -\beta_n(1-s) \\ -v_n & -v_t & 1 \end{bmatrix} \begin{bmatrix} N \\ T \\ Y \end{bmatrix} = \begin{bmatrix} K_n \\ K_t + \bar{E}_t \\ O \end{bmatrix},$$

where $K_n = \gamma_n + \bar{G}_n + \bar{J}_n$ and $K_t = \gamma_t + \bar{G}_t + \bar{J}_t$. Solving this system and calculating the value added multiplier (M) leads to

$$(23) \quad M = \frac{1}{v_t} \frac{dY}{d\bar{E}_t} = [1 - a_{nn} + (v_n/v_t)a_{nt}]/A,$$

where $A = [1 - a_{tt} - \beta_t(1-s)v_t][1 - a_{nn} - \beta_n(1-s)v_n] - [a_{nt} + \beta_n(1-s)v_t][a_{tn} + \beta_t(1-s)v_n]$.

The numerator of (23) is identical to that derived from the S-I-O multiplier (10). The multiplier differs from the S-I-O multiplier only in that the region's demand for tradables now enters the denominator. Moreover, because all the model coefficients are positive and lie between zero and unity, it is clear that A is less than the denominator in (10), and hence the closed I-O multiplier (23) is indeed larger.

By fixing the output of tradables rather than export demand, the S-I-O is equivalent to the closed I-O model when β_t , a_{tn} , and a_{tt} are set equal to zero. The reader can readily verify this by substituting these zero assumptions into (23) to obtain the multiplier in (10).

The classic open I-O multiplier in which household demand is exogenous can now be derived by setting $\beta_t = \beta_n = 0$ in (23). This leads to

$$(24) \quad M_p = \frac{1 - a_{nn} + a_{nt}(v_n/v_t)}{(1 - a_{nn})(1 - a_{tt}) - a_{nt}a_{tn}}.$$

The only difference between (24) and its S-I-O counterpart in (11) lies in the denominator. The two production linkage multipliers are identical when $a_{tt} = a_{tn} = 0$.

Magnitudes

In practice, estimates of agricultural growth multipliers have ranged widely. But, because

practitioners rarely apply different models to the same data set, it is unclear how much of the difference in the multipliers is due to differences in modeling approaches and how much arises because of variations in the underlying economic structure of the regions studied.

To provide consistent comparisons of the different fixed-price models, we apply them all to the same three data sets. Table 1 contains social accounting matrices (SAMs) for three contrasting regions: a low-income, subsistence-oriented agricultural economy (rural Sierra Leone); a middle-income, commercialized agricultural area (the Muda River region in Malaysia); and a high-income, diversified regional economy (Oklahoma state in 1959). In each case, agriculture dominates the regional economy. Yet, input intensity, the level of agroprocessing and trade, and the diversification of nonfarm activity contrast widely among the regions.

The three SAMs provide all but one of the parameters required for the fixed-price models.⁴ The exception, the marginal budget shares (β 's), come from household expenditure studies in Muda (Hazell and Roell) and Sierra Leone (King and Byerlee). The absence of such studies in Oklahoma required educated guesses as to the β 's based on average budget shares available in the SAM. Table 2 displays the fixed-price model parameters obtained for each region.

The empirical results, displayed in table 3, suggest four principal conclusions about fixed-price multipliers.⁵ First, the I-O model produces unrealistically large multipliers. It projects indirect income increments five to ten times as large as its S-I-O counterparts. Consider the difference in Sierra Leone, where the S-I-O model projects \$0.35 indirect income from a \$1 initial injection of tradable income, while the I-O multiplier places the indirect increment ten times as high, at \$3.01. The dramatically different scale arises because the I-O model allows an initial injection of tradable income to stimulate demand not only for nontradables but for more tradables as well. The resulting I-O multipliers

⁴ Because equation (5) assumes that the marginal equals the average leakage ratio, it, too, is available from the SAMs.

⁵ The 1.71 Muda multiplier with 83% consumption linkages reported in table 3 differs from the 1.83 multiplier with 60% consumption linkages reported by Bell, Hazell, and Slade. These differences arise because Bell, Hazell, and Slade (a) simulated the impact of paddy-driven agricultural growth whereas the estimates in table 3 assume an across-the-board increase in the output of all tradables, and (b) adjusted the input-output coefficients for technological change whereas they are held constant in the table 3 estimates.

Sources: The Muda SAM was aggregated from table 5.4 in Bell, Hazell, and Slade; nontradables were defined as the aggregate of accounts (19), (21), (22), (24)–(36), (38)–(44); and tradables as the aggregate of sectors (10)–(18), (20), (23), and (37). The Oklahoma SAM was aggregated from table 1 in Little and Doeksen; tradables were defined as the aggregate of the agricultural, agricultural processing, manufacturing, and mining sectors; and nontradables as the aggregate of the government accounts and all remaining productive activities except construction, which was classified as investment and entered in the capital account. The Sierra Leone account was synthesized from a variety of sources, including Matlon et al., Chuta and Liedholm, and King and Byerlee. We do not know the total value of transactions for rural Sierra Leone, hence the SAM is estimated for a gross tradable output of 100.

^a The tradables account does not include direct import of finished goods, which enter the rest-of-the-world account.

^b Includes trade with the nonregional economy, but also institutional accounts (6)–(8) in Muda.

^c Figures in parenthesis are the value of direct imports from outside the region. Any trade and distribution margins are included in the nontradable account.

are excessively large if, as many believe, aggregate agricultural output is supply-constrained in developing countries.

Second, the EB model offers a useful approximation to the S-I-O. Given the ease of computation, it is very attractive, at least as a first approximation to the S-I-O. It produces estimates only slightly worse than Hazell's simplified S-I-O and requires only one parameter instead of four.

Third, comparing linkages across regions, table 3 indicates that the S-I-O multipliers differ substantially, ranging from 1.35 in Sierra Leone to 1.71 in Muda to 2.23 in Oklahoma. Progressively greater input intensity, processing link-

ages, higher income, and consequently increasing consumption diversification into nonfoods account for the substantial spread.

Finally, consumer demand emerges as consistently more important than production linkages, with consumption linkages ranging from 80%–90% of the total multiplier in Muda and Sierra Leone to 60% in Oklahoma. Findings from elsewhere unanimously corroborate the predominance of consumption over production linkages (e.g., Gibb; Bell, Hazell, and Slade; Haggblade and Hazell). Even in low-income regions where consumption linkages are feeble, production linkages tend to be still smaller. This is particularly true in Sub-Saharan Africa, where con-

Table 2. Coefficients for Fixed-Price Models

^a Derived from the SAMs in table 1.

^b Derived from the SAMs in table 1 by assuming the marginal equals the average leakage ratio.

^c Based on estimates from the following sources: Muda (Hazell and Roell); Sierra Leone (King and Byerlee); Oklahoma projections based on average budget shares. Hazell and Roell report a β_n of 0.4 for Muda, but we increased this to 0.5 to include fresh fruits and vegetables which are produced by "other agriculture," and are classified as a nontradable sector in table 1. Note that $\beta_n + \beta_i$ is less than unity in all cases; the difference is the marginal budget share for direct imports.

sumption linkages are much smaller absolutely than in Asia; however, because production linkages are even lower, the relative share of con-

sumption linkages remains larger (Haggblade and Hazell).

Limitations of the Fixed-Price Models

Fixed-price models are attractive because they are relatively easy to estimate and solve. But the underlying assumption of a perfectly elastic supply of nontradables, common to all fixed-price models, is troublesome. In developing countries, rural nontradables are mostly services or local manufactures produced by small, labor-intensive firms. Given a plentiful supply of labor, a common feature in Asia but also possible in Africa during slack periods in the agricultural calendar, it is reasonable to suppose the short-run supply elasticity of nontradables may be high. Moreover, the low incremental capital-output ratios reported by many researchers for rural nonfarm businesses suggest that even the long-run supply elasticity may be large since firms can expand their capacity with the aid of capital available from retained profits.

But these conditions will not always be met, as the increasing real wages in many successfully growing rural areas attest. In such cases, the supply of nontradables will be upward sloping and part of any agriculture-led increase in demand for nontradables will be dissipated through price inflation. So the multipliers derived from fixed-price models will overestimate the amount of indirect income generated within

Table 3. A Comparison of Fixed Price Income Multipliers in Three Regions

the regional economy. To correct for this bias requires a price-endogenous model.

A Price-Endogenous (PE) Model

The Model

The proposed model relaxes the two key simplifying assumptions of fixed-price models. First, it allows for increasing-cost nontradable supply by incorporating the two most likely sources of rising nontradable prices. One stems from an upward-sloping labor supply curve facing the region. As the demand for nontradables grows, their increased production increases the regional demand for labor, thereby increasing the nominal wage rate and the average cost of nontradables. The other source of price increase arises from the possibility that capacity constraints and fixed factors, in the short run, lead to diminishing returns in variable inputs and hence to rising average cost as output increases.

Second, to allow less extreme assumptions about input substitution, the proposed price-endogenous model imposes no specific functional form on the production technology. The ensuing empirical applications, however, include a Leontief specification as a special case in order to permit comparison with the fixed-price models.

Following, where possible, the notational conventions used above, the price endogenous model can be written as follows:

for labor in sector j ; π_j , the profit function for sector j ; and θ , a technology shift parameter for production of tradables.

Equations (25) and (26) define market clearing in tradables and nontradables, respectively. Unlike their fixed-price counterparts, equations (2) and (19), market supply now responds to output prices and the nominal wage. Investment and government expenditure remain exogenously determined and, as in the S-I-O model, net exports are a residual. Because there is no balance-of-payments constraint, equation (25) is not part of the simultaneous portion of the solution; it drops out as it did in the S-I-O model.

The labor market representation (27) has no explicit counterpart in the fixed-price models. It is required here to determine the endogenous wage rate. Note that households' willingness to supply labor depends on the real rather than the nominal wage rate.

Regional income (30) now has two components. The first includes profits, that is, returns to fixed factors in each sector. The second includes total wage income, wL_s . In contrast to the fixed-price models where value added (profits plus wage payments) remains a fixed share of gross output in both sectors, the price-endogenous model makes no such presumption.⁶

As with the fixed-price models, we are primarily interested in deriving the income multiplier resulting from a technological shift in the supply of tradables. Note that θ , the technology shift parameter, affects the tradable sector's de-

$$\begin{aligned}
 (25) \quad T(P_t, P_n, w, \theta) &= H_t(P_t, P_n, Y) + D_m(P_t, P_n, w) + D_n(P_t, P_n, w, \theta) \\
 &\quad + \bar{G}_t + \bar{J}_t + \bar{E}_t && \text{tradables,} \\
 (26) \quad N(P_t, P_n, w) &= H_n(P_t, P_n, Y) + D_n(P_t, P_n, w, \theta) + D_m(P_t, P_n, w) \\
 &\quad + \bar{G}_n + \bar{J}_n && \text{nontradables,} \\
 (27) \quad L_s(\bar{w}) &= L_{dt}(P_t, P_n, w, \theta) + L_{dn}(P_t, P_n, w) && \text{labor market,} \\
 (28) \quad \bar{w} &= w/l && \text{real wage,} \\
 (29) \quad l &= P_n^b P_t^{1-b} && \text{cost of living index,} \\
 (30) \quad Y &= \pi_t(P_t, P_n, w, \theta) + \pi_n(P_t, P_n, w) + wL_s && \text{income.}
 \end{aligned}$$

Notation new to the price-endogenous model includes D_{ij} , the intermediate demand by sector j for the output of sector i ; P_t , the price of tradables, presumed as before to be fixed outside the region; P_n , the price of nontradables; the nominal and real wage rates, w and \bar{w} , respectively; l , a cost of living index; b , the share of nontradables in total household income; L_s , the regional labor supply function; L_{dj} , the demand

mand for labor and intermediates as well as its supply function. This formulation provides the flexibility needed to experiment with different types of technological change, although, as with

⁶ In the specific experiments that follow, using Cobb-Douglas technology or Leontief technology with fixed prices, the constancy of value-added shares does remain.

the fixed-price models, we limit ourselves here to forms of investment or technological change that do not affect the use of intermediate goods per unit of tradable output.

Substituting the real wage rate (28), cost-of-living index (29), and income definition (30) into the nontradable (26) and labor market equations (27), totally differentiating with respect to the price of nontradables (P_n), the wage rate (w), the exogenous change in technology (θ), and expressing all variables in percentage change terms (\cdot) leads to⁷

$$(31) \quad \begin{bmatrix} \xi_{P_n}^N - \xi_{P_n}^{H_n} \alpha_n - \xi_{P_n}^{D_{nt}} \alpha_{nt} - \xi_{P_n}^{D_{nn}} \alpha_{nn} & \xi_w^N - \xi_w^{D_{nt}} \alpha_{nt} - \xi_w^{D_{nn}} \alpha_{nn} & 0 & -\xi_Y^{H_n} \alpha_n \\ \xi_{P_n}^{L_{dt}} (1 - \lambda_n) + \xi_{P_n}^{L_{dn}} \lambda_n & \xi_w^{L_{dt}} (1 - \lambda_n) + \xi_w^{L_{dn}} \lambda_n - \xi_w^{L_s} & \xi_{\tilde{w}}^{L_s} & 0 \\ -b & 0 & 1 & 0 \\ -\mu & -d\xi_w^{L_s} & d\xi_w^{L_s} & 1 \end{bmatrix} \begin{bmatrix} \hat{P}_n \\ \hat{w} \\ \hat{f} \\ \hat{Y} \end{bmatrix} = \begin{bmatrix} \frac{\partial D_{nt}}{\partial \theta} \cdot \frac{1}{N} \\ -\frac{\partial L_{dt}}{\partial \theta} \cdot \frac{(1 - \lambda_n)}{L_{dt}} \\ 0 \\ \frac{\partial \pi_t}{\partial \theta} \cdot \frac{1}{Y} \end{bmatrix} d\theta,$$

where new notation includes ξ_j^i , the elasticity of i with respect to j ; shares of gross nontradable output consumed by households ($\alpha_n = H_n/N$) or used as intermediates in nontradable ($\alpha_{nn} = D_{nn}/N$) and tradable production ($\alpha_{nt} = D_{nt}/N$); the proportion of regional labor force employed in nontradables ($\lambda_n = L_{dn}/L_s$); share of regional income spent by households on nontradables ($b = H_n P_n/Y$); wage share of regional income ($d = w L_s/Y$); and the proportion of regional income spent on total final demand for nontradables $\mu = (H_n + \bar{G}_n + \bar{J}_n) P_n/Y$.

Solution of (31) tracks comparative static changes in the two endogenous variables, P_n and w , resulting from the technology shift parameters on the right-hand side. In turn, the changes in labor and nontradable market equilibria generate changes in inflation and regional income according to the bottom two equations in (31). Stability of the system requires that the determinant of the 4×4 coefficient matrix be negative.

Defining the Multiplier

The price-endogenous multiplier is defined as the total increase in real regional income compared to the initial technologically induced increase in tradable income.

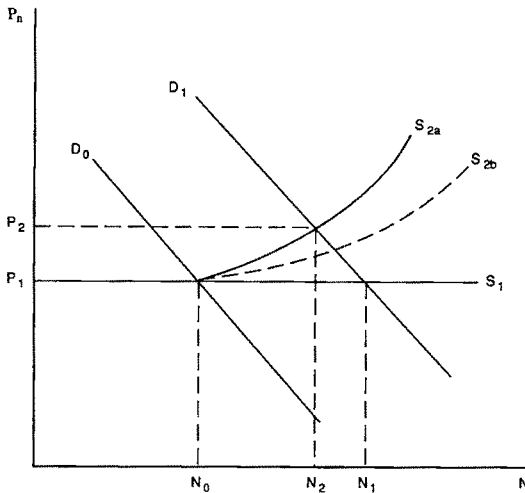

$$(32) \quad M = \frac{\frac{dY}{d\theta} - (N - D_{nn} - D_{nt}) \frac{dP_n}{d\theta}}{\frac{\partial Y}{\partial \theta}}.$$

Unlike the fixed-price models, where no inflation occurs, the price-endogenous model requires a deduction for inflation. The second term in the numerator of (32) represents the increase in the cost of nontradables consumed within the region.⁸ It must be deducted from the total income increase, since we are interested in the change in real rather than nominal income.

Figure 1 pictures the difference between the fixed-price and price-endogenous multipliers. In a fixed-price world, a given increase in technologically induced tradable income will stimulate additional nontradable income equivalent to $(N_1 - N_0)P_1$ times the value added ratio v_n . But when nontradable supply is not perfectly elastic, the same initial increment in tradable income will generate only $(N_2 - N_0)P_1 v_n$ in nontradable earnings. Thus, the upward-sloping nontradable supply dampens the real income

⁷ Derivation of (31) makes use of the following relationships from Sheperd's lemma: $\partial \pi_t / \partial P_n = -D_{nt}$, $\partial \pi_t / \partial P_n = N - D_{nn}$, $\partial \pi_t / \partial w = -L_{dt}$, and $\partial \pi_t / \partial w = -L_{dn}$.

⁸ In computing the real change in regional welfare, we have opted to deduct the entire increase in the cost of nontradables designated for final demand. In addition to households, government and investors consume some nontradables. Because they may or may not be residents of the region, others may wish to deduct only the increased nontradable cost borne by regional residents.

S_1 assumes perfectly elastic supply of labor and nontradables (S-I-O, PE1);

S_{2a} assumes short-run, fixed inputs in nontradables, Leontief technology (PE2a);

S_{2b} assumes short-run, fixed inputs in nontradables, Cobb-Douglas substitutability among intermediates (PE2b)

Figure 1. Graphical comparison of fixed-price and price-endogenous multipliers

multiplier by $(N_2 - N_1)P_1v_n$. Note that calculating the real income multiplier requires deducting the inflation $(P_2 - P_1)N_2 = (N - D_{nn} - D_{nt})dP_n$ from the total nominal income increase in the price-endogenous case.

Economic Interpretation of the Multiplier

The existence of a multiplier depends on drawing unused or underused resources into more productive economic activity. In figure 1, the increase in nontradable output, to either N_1 or N_2 , requires pulling labor, intermediates and in the long run more fixed inputs into nontradable production. To attract resources from other competing uses, including leisure, requires that they earn higher returns in nontradable production.⁹

⁹ The multiplier is defined in terms of income, not utility. A utility-based measure would yield no increase in welfare as a result of a marginal shift of labor out of leisure and into the labor market. Yet the shift from leisure to labor does increase national income. Moreover, welfare will also increase following a finite, as opposed to marginal, increase in labor supply. This will show up as an increase in producer surplus to suppliers of labor.

Formally, the multiplier defined in (32) can be rewritten as follows:¹⁰

$$(33) \quad M = \frac{\frac{\partial \pi_t}{\partial \theta} + w \frac{\partial L_s}{\partial \bar{w}} \frac{d\bar{w}}{d\theta}}{\frac{\partial \pi_t}{\partial \theta} + w \frac{\partial L_{dt}}{\partial \theta}}.$$

It differs from unity to the extent that

$$\frac{\partial L_s}{\partial \bar{w}} \frac{d\bar{w}}{d\theta} \geq \frac{\partial L_{dt}}{\partial \theta}.$$

Thus, the existence of the multiplier depends on drawing some labor into nontradable production. When this happens, the total increase in labor supply (L_s) exceeds the increased labor demand in tradables alone (L_{dt}). Although this formulation centers around the labor market, it implicitly requires that producers similarly draw additional intermediates, and in the long-run fixed factors, into nontradable production.

This derivation yields a surprisingly simple operational means of estimating price-endogenous regional income multipliers resulting from an agricultural project. In addition to project income and employment, an analyst would only require the change in regional employment in nontradables as well as the initial wage rate. Both employment and wage data are relatively easy to obtain, certainly more easily obtainable than changes in total regional income. This does not imply that the multiplier is composed solely of increased wage earnings in nontradables. Profits and returns to fixed factors increase as well. But, through the substitutions from Shepherd's lemma, these portions of the total change in regional income cancel out, because they represent transfers from consumers to producers.

Parameters for Four Experiments

To estimate a price-endogenous income multiplier for a particular region requires data for the twenty-three model parameters in equation (31); twenty parameters in the large matrix and three technology shift parameters on the right-hand side. Of the twenty-three parameters, five of the shares (α_{nn} , α_{nt} , α_n , b , and μ) can be computed

¹⁰ The numerator in (33) is obtained by totally differentiating (30) w.r.t. θ , substituting the results from Shepherd's lemma given in footnote 7, and subtracting the inflation term $(N - D_{nn} - D_{nt})dP_n/d\theta$. The denominator in (33) is obtained by substituting $L_{dt} + L_{dn}$ for L_t in (30), and then taking the partial derivative: $\partial \pi_t / \partial \theta$.

directly from the SAMs. The remaining eighteen must be obtained from outside sources, although economic theory and features of production technology impose a series of restrictions on them. These restrictions and their derivation for the specific functional forms used in this paper are available on request from the authors. Table 4 summarizes the estimated parameter values that apply to each of the three rural regions under review.¹¹

Four variants of the price-endogenous model (*PE1* – *PE4*) permit contrast with their fixed-price relatives by progressively relaxing each of the fixed-price model assumptions. The first, *PE1*, adopts assumptions approximating those of the S-I-O model. It takes supply of both labor and nontradables to be perfectly elastic and specifies Leontief technology in all inputs. The second, *PE2*, introduces an upward-sloping supply of nontradables while maintaining a highly elastic supply of labor. This situation, the one depicted by the supply curve 2a in figure 1, arises in the short run when nontradable producers operate with plants at full capacity and can only increase output at increasing cost. In contrast, *PE3* presumes that labor supply rather than fixed capacity dampens multipliers by raising cost (P_n) via increasing wages. Equivalent to a situation of excess capacity in nontradables, or a long-run time horizon which allows firm entry in nontradables, *PE3* best describes a rural economy during peak agricultural seasons. *PE4* depicts a doubly constrained rural economy in which both the labor supply and nontradable production cost functions slope upwards.

To relax the restrictive S-I-O assumption of fixed-coefficient Leontief production technology, *PE2* and *PE4* include two variants. The first of these, *PE2a* and *PE4a*, retain Leontief technology. But the second pair, *PE2b* and *PE4b*, introduce input substitutability by specifying Cobb-Douglas production technology in all inputs. Expanding substitution possibilities in this way increases nontradable output supply elasticity. By allowing firms to substitute labor for intermediates as the price of nontradable intermediates (P_n) rises, firms are able to increase output at lower cost than would otherwise be possible. The expanded substitution set corresponds to nontradable supply curve 2b in figure 1. It illustrates graphically how allowing for in-

put substitution offsets some of the dampening projected by the price-endogenous multipliers.

Empirical Results

In comparing the series of price-endogenous multipliers with the fixed-price barometer, the S-I-O model, three results are anticipated. First, *PE1*, because it maintains all the perfect elasticity assumptions of the S-I-O, should yield the highest multiplier and it should be equivalent to the S-I-O.¹² Second, the multiplier should be smallest when both labor supply and plant capacity constrain, that is, in *PE4*. In this setting, both wage and price inflation will compound increases in P_n and therefore dampen the multiplier most. Finally, increasing prospects for input substitution should increase nontradable supply elasticity and thus the output response relative to fixed-coefficients technology. Hence, we expect that the multiplier for *PE2b* will be greater than that in *PE2a* and that *PE4b* will exceed *PE4a*. But the ranking of *PE2* and *PE3* cannot be determined a priori. It will depend on the parameters for the specific region in question.

Table 5 bears out these predictions by comparing the multipliers generated in each of the four price-endogenous model experiments. Using data for the three regional economies, Sierra Leone, Muda River region of Malaysia, and Oklahoma, it presents not only multipliers but also the income, wage, and price increases projected in each scenario.

How overoptimistic are the fixed price models? As expected, the answer depends on what is driving the rising price of nontradables. In the worst-case scenario, *PE4a*, the indirect income increment falls dramatically to 20%–40% of the semi-input-output projection (table 5). But after accommodating prospects for input substitution, in *PE4b*, the indirect income increases to 50%–60% of the S-I-O.

In the more likely intermediate situations, *PE2b* and *PE3*, table 5 suggests that price endogeneity will reduce regional indirect income increments to 75%–90% of the S-I-O level. Not surpris-

¹¹ Note that $\partial D_n / \partial \theta \neq 0$ in table 4. Because the commodity demands are written in indirect form in equations (25) and (26), θ must be used to drive increased intermediate demands for tradables production even when the input-output ratios are assumed to remain constant.

¹² For each region, we have calibrated *PE1* to its S-I-O counterpart by making small adjustments in the wage shares of regional income (d). We began with very fragmentary labor share data, often enterprise budgets for selected activities, and sometimes from similar types of agriculture in other countries. Using these as rough approximations generated *PE1* multipliers within 5%–10% of the S-I-O. Because *PE1* approximates the S-I-O when labor supply and output supply are perfectly elastic, this calibration seemed the most plausible procedure for firming up the labor share data.

Note: A blank cell takes the value of the closest nonblank cell to its left. Models PE1 and PE3 assume Leontief technology in all inputs, while models PE2 and PE4 consider varying degrees of input substitutability. The "b" variants (PE2b and PE4b) ensure full input substitution via Cobb-Douglas technology in all inputs. The "a" runs (PE2a and PE4a) simulate the fixed-price model assumptions of Leontief technology in intermediates but introduce Cobb-Douglas substitutability in other inputs. Economic theory and these production function specifications impose a series of restrictions on the table parameters. These restrictions and their derivation are available, on request, from the authors.

^a The following 5 parameters are equal to zero and are not listed in the table: ξ_{Pn}^{Ln} , ξ_{Pn}^{Ln} , ξ_{Pn}^{Ln} , ξ_{Pn}^{Ln} , and $\partial L_{ni}/\partial \theta$

\hat{f}	.3	5.3	3.8	2.2	5.0	4.1

Note: All units are percentages except the multipliers which are in units of local currency. PE1 is equivalent to the S-I-O model and has Leontief technology and highly elastic supplies of labor and nontradables; PE2a has a highly elastic supply of labor but an upward-sloping supply of nontradables; PE3 has a highly elastic supply of nontradables but an upward-sloping supply of labor; PE4a has upward-sloping supplies of labor and nontradables; and PE2b, PE4b assume Cobb-Douglas technology rather than the Leontief technology of their PE2a and PE4a counterparts. See the text for a more detailed discussion of the assumptions underlying each experiment.

^a Compares the income increment for each multiplier with that from the S-I-O.

ingly, the magnitude of the dampening varies across regions. In the long run, when firm entry allows highly elastic nontradable output responses (PE3), the Muda Region multiplier remains highest, at roughly 90% of the S-I-O level, because of its very elastic labor supply. In contrast, the long-run multipliers in Sierra Leone and Oklahoma fall to 75%–85% of the S-I-O predictions, primarily because of less elastic regional labor supplies.

Conclusions

The existence of agricultural growth multipliers ultimately depends on drawing additional resources into nontradable activity. Hence, the elasticity of nontradable supply is crucial to the size of the multipliers.

Where labor supply is elastic and capacity does not constrain nonfarm activity, fixed-price models are appropriate. Among them, the semi-input-output model offers the best estimate of regional growth linkages. As a rough and ready indicator, the simple one-parameter economic base model offers projections surprisingly close to the semi-input-output model. In contrast, the input-

output model generates unrealistically large multipliers for most rural third world settings.

But price endogeneity may reduce multipliers substantially. Because fixed capacity constraints seem less binding, especially in the long run, labor supply is probably the crucial determinant of the multipliers. If so, our estimates suggest that, as a rough rule of thumb, the Asian multipliers lie in the range of 90% of the levels projected by semi-input-output models, while the African multipliers stand at closer to 75% of the fixed-price estimates.

Private Property Rights and Forest Preservation in Karnataka Western Ghats, India

M. G. Bhat and R. G. Huffaker

Areca nut orchard owners have been mulching their orchards with foliage from surrounding government-owned deciduous forests at an average rate that may well deplete foliage within a decade, thereby endangering the long-term viability of the region's most profitable agricultural enterprise. A bioeconomic model of areca nut production is formulated to determine the circumstances under which privatization of forest resources in the hands of orchard owners will stem this rapid depletion. An empirical application suggests that foliage is not currently sufficiently abundant to survive privatization; however, the prospects for preservation can be increased with the imposition of a preprivatization period of regulated use.

Key words: India, optimal extinction, privatization, sustainable agriculture.

This paper considers whether converting hillside forests bordering the areca nut-growing belt of Karnataka Western Ghats in India from government to private ownership by areca nut orchard owners would encourage the sustainable use of forest products in areca nut production and thus stem the rapid depletion occurring under the current use system. The paper represents an application of the recent literature in optimal extinction of renewable resources to study the sustainability of an endemic production process in a part of the world receiving considerable attention by agricultural and resource economists.

We begin the paper by describing the study area and the resource-use problem, then formulate a normative decision model that specifies how a representative orchard owner should harvest foliage from the privately owned section of forest to maximize the present value of areca nut production. We then examine when a sustainable harvest policy is present-value superior to a depletive policy resulting in eventual exhaustion of the foliage stock, under various assumptions about both biological and economic parameters. Finally, by employing economic and environmental data collected from case studies

in the region, we simulate optimizing behavior under private ownership. Assuming that the normative model is valid, the simulations are indicative of the bioeconomic circumstances under which private ownership by areca nut producers is a feasible strategy for preserving forest resources in the study region.

Problem Development

Over the past century, farmers in Karnataka Western Ghats in India have broadened narrow valleys annually by cutting into adjoining hillsides and spreading soil to create terraces. Terraces are privately held and comprised of areca nut orchards (generating the highest economic returns) and crop and paddy lands. Major sources of irrigation water include perennial and seasonal streams flowing through the valleys. The deciduous forests and grasslands covering the hillsides are government-owned and separated into *soppinabetta* (*soppu* = leaf and *betta* = hill) and minor forest.

The *soppinabetta* is essential for the supply of green and dry leaves used to form the farmyard-manure-and-mulch combination that serves to conserve moisture and retard soil erosion in areca nut orchards. The government traditionally has given orchard owners exclusive right in the *soppinabetta* to prune trees for leaves and twigs and to sweep dry leaves from the forest

M. G. Bhat is a graduate research assistant in the Department of Agricultural Economics, University of Tennessee. R. G. Huffaker is an assistant professor, Department of Agricultural Economics, Washington State University, formerly Department of Agricultural Economics, University of Tennessee. Senior authorship is not assigned.

floor. Orchardists also have been allowed to take small timber for fuel and to graze their animals on the grasslands. However, they have not been given the right to chop down large trees or to sell any of the *soppinabetta* products. The government has left orchard owners to divide the *soppinabetta* among themselves by mutual agreement. As a result, each acre of areca nut orchard is supported by about six acres of *soppinabetta*. In contrast, minor forest lands have been reserved for the fuel, leafy matter, and small timber needs of all villagers.

An ecological case study of Karnataka Western Ghats by Gadgil investigated the impact of the utilization of the region's renewable resources (soil, surface and ground water, and plant biomass) on the five major categories of land (crop lands, orchards, *soppinabetta*, minor forest, streams and ponds) for signs of ecological imbalance.¹ Gadgil found that ecological imbalances are related to the pattern of ownership. Government-owned *soppinabetta*, minor forest, and streams and ponds tend to suffer more from the ill effects of imbalanced resource use than privately held orchards and crop land. For example, the success of orchard owners in maintaining soil moisture and inhibiting erosion in areca nut orchards has resulted in an average annual recovery rate of *soppinabetta* foliage biomass (6 tonnes per hectare) that is twice the average annual replenishment rate. Gadgil estimated that this imbalance would deplete the foliage biomass within a decade.

Gadgil briefly discussed two policy options for preserving *soppinabetta* resources. One option is to convert the *soppinabetta* into private ownership by areca nut orchard owners in hopes of achieving the same balanced resource use occurring on privately held lands. The other is to convert the *soppinabetta* into community ownership with community-control systems designed to "ensure serving the objective of preservation of ecological balance with measured benefits to the participants" (p. 386).

A logical first step in deciding which option should be adopted is to determine when private ownership by areca nut producers is a feasible preservationist strategy. Hence, this paper considers the bioeconomic circumstances under which private ownership may lead to ecologically balanced "continuous" use and preserva-

tion of *soppinabetta* resources. A comparison of the relative performance of private ownership versus community ownership and control is beyond the scope of this paper.

The methodology employed depends on the owners' management criterion and the primary productive use they will make of *soppinabetta* resources. Following Clark, the sole owner is assumed "to view the stock as a capital asset; [and thus to manage according to] the standard cost-benefit criterion of maximizing present values of net economic revenues" (pp. 3, 4). Present-value maximization is also a relevant criterion for a community control system; however, the specification of costs and benefits must be expanded to include those external to the sole owner's decision-making environment. This paper's attention is limited to sole-owner behavior because available survey data provide some information on the private net benefits of areca nut production but none on the type or extent of external net benefits (Gadgil; Gadgil, Hedge, and Bhoja Shetty; Hulgol Service Co-operative Society).

The primary productive use areca nut orchard owners will make of *soppinabetta* resources depends on the bundle of property rights that they inherit and on the relative value of alternative outputs. For example, if the bundle includes the right to chop down large trees to sell as lumber, and this is the most lucrative use, then utilization must be studied primarily as a forest rotation problem. Alternatively, if chopping down large trees remains illegal, or areca nut production remains the most valuable use regardless of the legality of harvesting large trees, then utilization must be studied primarily as a conversion of foliage biomass to orchard production. This paper chooses to study the potential for foliage preservation under orchard production because it is the current use and information is available from case studies on the production process and on input/output prices.

A Bioeconomic Model of Areca Nut Production

Consider a representative areca nut producer who mulches one-sixth of an acre of orchard with the foliage biomass generated by an exclusively owned acre of *soppinabetta*. Let $B(t)$ (kilograms per acre, kg/ac) denote foliage density and $R(t)$ (kg/ac/t) the recovery (harvest) rate in year t , where $B, R \geq 0$. Then, following the general

¹ An ecological imbalance occurs when a resource stock decreases over time because it is depleted faster than it can be naturally replenished or when a resource stock accumulates over time because its input rate exceeds its removal rate.

framework of Smith, the dynamics of foliage biomass are governed by

$$(1) \quad \dot{B}(t) = G(B) - R,$$

where $G(B)$ (kg/ac/t) represents the average annual growth (production) of foliage biomass by the forest and is characterized by density dependence and a "minimum viable" biomass stock. Density-dependent growth implies that marginal foliage production tends to increase at low biomass densities but decrease at high densities because of heavier specific competition for vital resources, especially sunlight. The minimum viable biomass stock implies that a forest defoliated on average beyond this level will eventually die out, even if harvesting ceases beforehand. Biomass levels below the minimum viable stock require the forest to refoliate in the same growing season. This, in turn, causes it to begin the next season with low carbohydrate reserves, fewer and less productive leaves, and increased susceptibility to attacks by pathogenic organisms (Wargo, Kramer and Kozlowski).

Density dependence is imposed by requiring $G(B)$ to be strictly concave for $B \geq 0$. The minimum viable stock, \underline{B} , is created by requiring $G(B)$ to have a pair of biomass-axis intercepts, $G(\underline{B}) = G(\bar{B}) = 0$, where $0 < \underline{B} < \bar{B}$. Given an initial biomass level $B_0 > \underline{B}$, the stock tends toward \bar{B} (the carrying capacity) in the absence of recovery. The following generalized logistic equation meets these requirements

$$(2) \quad G(B) = -a_0 + a_1 B - bB^2.$$

A problem with (2) is that it allows a biomass level of zero to decline since $G(0) < 0$. However, this problem can be overcome, while preserving the strict concavity and smoothness of $G(B)$, by imposing the constraint $B \geq 0$ explicitly in optimization (Lewis and Schmalensee, footnote 2). The biomass-axis intercepts are given by

$$(3a) \quad \underline{B} = (1/2b) [a_1 - \sqrt{a_1^2 - 4a_0b}]$$

$$(3b) \quad \bar{B} = (1/2b) [a_1 + \sqrt{a_1^2 - 4a_0b}].$$

Maximum sustained biomass yield occurs at $B_{msy} = a/2b$.

Let $A(R)$ [kg/(1/6)ac/t] represent annual areca nut production on one-sixth of an acre of orchard land. $A(R)$ is assumed to vary solely with recovered foliage biomass; all other inputs are applied in fixed proportions. Positive but diminishing marginal returns to the application of

biomass are assumed; hence $A_R(R) > 0$, and $A_{RR}(R) < 0$, where the subscripts denote differentiation. $A(R)$ has a horizontal asymptote at the maximum periodic production level \bar{A} . The Michaelis equation meets these conditions and is convenient for analytical use:

$$(4) \quad A(R) = \bar{A}(1 - e^{-\alpha R})$$

where α is a positive parameter and q is the fraction of recovery made up solely of leaves (i.e., excluding twigs).

Let p (rupees per kilogram, Rs/kg) denote the constant unit selling price of areca nuts and $C(B)$ (Rs/kg) the cost per unit of biomass recovery. An inverse relationship is assumed between unit recovery costs and biomass to reflect the additional labor required to prune limbs of greater height as foliage biomass decreases, i.e., $C_B(B) < 0$. Moreover, a finite vertical intercept, c_0 , is assumed so that the possibility of extinction as a present-value-maximizing policy is not ruled out a priori. Finally, unit costs are assumed to asymptotically approach zero as biomass increases. An exponential cost function satisfies these characteristics

$$(5) \quad C(B) = c_0 \exp(-c_1 B),$$

where c_1 is a positive parameter.

Periodic profits (Rs/ac/t) generated by employing *soppinabetta* resources in areca nut production are

$$(6) \quad \pi(t) = pA(R) - C(B)R - FC,$$

where FC represents the unavoidable costs of fixed factors associated with areca nut production (mainly pesticide).² The present value of the stream of profits over the interval $0 \leq t \leq T$ is

$$(7) \quad PV = \int_0^T \pi(t)e^{-rt} dt,$$

where r is the real annual discount rate.

The producer's problem is to select a function $R(t)$ and a scalar T that maximizes (7) subject to (1), the nonnegativity of R and B , and a given initial biomass level, $B(0) = B_0$. Following Takayama (theorem 8.C.1), the lagrangian function for this problem is written as

$$(8) \quad L[B, R, \gamma_1, \gamma_2] \\ = H[B, R] + \gamma_1 R + \gamma_2 [G(B) - R],$$

² The present value function does not include the producer's savings generated by using recovered twigs as fuel. Such savings are minor in comparison to profits from areca nut production, and their addition significantly obscures the analytical results.

where $H[B, R]$ is the current-valued hamiltonian measuring the flow of annual net benefits

$$(9) \quad H[B, R] = pA(R) - C(B)R + \lambda[G(B) - R],$$

$\lambda(t)$ is the costate variable measuring the marginal present value of biomass in areca nut production in each year, $\gamma_1(t)$ and $\gamma_2(t)$ are functions associated with the nonnegativity constraints on R and B , and $[G(B) - R]$ is the effective nonnegativity restriction on B .

Solution functions R, λ, B must solve the system of Pontryagin necessary conditions:

$$(10a) \quad L'(R) = pA'(R) - C(B) - \lambda + \gamma_1 - \gamma_2 = 0$$

$$(10b) \quad \dot{\lambda}(t) - r\lambda = -L'(B) = -[-C'(B)R + \lambda G'(B) + \gamma_2 G'(B)]$$

$$(10c) \quad L'(\lambda) = \dot{B} = G(B) - R,$$

the nonnegativity constraint qualifications on R and B (Takayama, theorem 8.C.1; Arrow and Kurtz, chap. 2, proposition 5)

$$(10d) \quad \gamma_1 \geq 0; \quad \gamma_1 R = 0$$

$$(10e) \quad \gamma_2 \geq 0; \quad \gamma_2 B = \gamma_2 [G(B) - R] = 0,$$

the free terminal-time transversality condition (Lewis and Schmalensee, p. 538)

$$(10f) \quad \lim_{t \rightarrow T} e^{-rt} H[B, R] = 0,$$

and nonnegativity restrictions on the terminal biomass level $B(T)$ if the optimal value of T is finite (Takayama, corollary to theorem 8.C.1; Lewis and Schmalensee, p. 538)

$$(10g) \quad \lim_{t \rightarrow T} e^{-rt} \lambda(t) \geq 0$$

$$(10h) \quad \lim_{t \rightarrow T} e^{-rt} \lambda(t) B(t) = 0.$$

When (10a)–(10c) can be satisfied by non-zero levels of R and B [so that γ_1 and γ_2 equal zero by (10d) and (10e), respectively], routine calculation converts (10a)–(10c) into two first-order differential equations in R and B :

$$(11a) \quad \dot{R} = \frac{C'(B)G(B) - [pA'(R) - C(B)][G'(B) - r]}{pA''(R)}$$

$$(11b) \quad \dot{B} = G(B) - R.$$

Recovery Strategies

Recovery strategies can be categorized according to the length of the underlying time horizon. Lewis and Schmalensee refer to infinite horizon strategies as continuous strategies, and finite horizon strategies as abandonment strategies. Infinite horizon strategies are continuous because they asymptotically approach a steady state of (11). Once reached, steady-state biomass and recovery levels are sustained through time by producing both ecological balance (where biomass is recovered at its rate of natural replenishment) and economic balance (where the producer has no further economic incentive to manipulate the recovery rate over time). Alternatively, finite horizon strategies veer away from steady states of (11), and thus ultimately result in the resource being abandoned after some finite time.

This section proceeds by characterizing: (a) the optimal continuous recovery strategy and its domain of feasible initial biomass levels, B_0 ; (b) the optimal abandonment strategy, its domain of feasibility, and when it results in eventual extinction of the stock; and (c) the superiority of one strategy over the other when their domains of feasibility overlap.

Optimal Continuous Recovery Strategy

A continuous recovery strategy, satisfying necessary conditions (10) and asymptotically approaching a steady state of (11), is optimal among all such policies if it satisfies the concavity conditions set out in Arrow and Kurtz (chap. 2, proposition 10). These conditions require that the Hessian matrix of second partial derivatives of the hamiltonian (9) with respect to B and R is negative definite when evaluated at steady state (B^*, R^*). Thus, the first principal minor must be negative:

$$(12) \quad |H_{RR}(R^*)| = pA_{RR}(R^*) < 0,$$

and the second principal minor must be positive:

$$(13) \quad \begin{vmatrix} H_{RR} & H_{RB} \\ H_{BR} & H_{BB} \end{vmatrix} = -pA_{RR}(R^*)[C_{BB}(B^*)R^* - \lambda(B^*, R^*)G_{BB}(B^*)] - C_B(B^*)^2 > 0,$$

where $\lambda(B^*, R^*)$ can be solved for using (10a).

Clearly, (12) holds given the assumed diminishing marginal productivity of foliage biomass in areca nut production. However, (13) is indeterminate, and thus will be numerically evaluated at the steady-state of interest in a later section of this paper.

A phase portrait in (R, B) space is useful for determining the configuration and stability of steady-state solutions of (11).

Foliage biomass zero-change isocline. The foliage biomass zero-change isocline (the locus of B, R combinations that balance growth with depletion and thus hold the biomass stock constant over time) is derived by setting \dot{B} in (11b) equal to zero and solving for R in terms of B ,

$$(14) \quad R(B)|_{\dot{B}=0} = G(B) = -a_0 + a_1 B - bB^2.$$

The biomass zero-change isocline (BI) is the annual growth function (2) and hence shares its properties.

Recovery zero-change isocline. The recovery zero-change isocline (the locus of B, R combinations holding recovery constant over time) is derived by setting $\dot{R} = 0$ in (11a) and solving for R in terms of B ,

$$(15) \quad R(B)|_{\dot{R}=0} = -(1/\alpha q) \ln \left\{ \frac{C_B(B)G(B) + C(B)[G_B(B) - r]}{\alpha q p \bar{A}[G_B(B) - r]} \right\}, \quad \text{or} \\ = -(1/\alpha q) \ln \left\{ \frac{c_0 \exp(c_1 B)[bc_1 B^2 - (a_1 c_1 + 2b)B + [a_0 c_1 + (a_1 - r)]]}{\alpha q p \bar{A}(a_1 - 2bB - r)} \right\},$$

in terms of (2), (4), and (5). The recovery zero-change isocline (RI) is considerably more complicated to characterize than the biomass isocline. This is the result of the restricted domain of the logarithmic function and the discontinuities that result when the numerator and denominator in its argument (bracketed term) are identically zero.

In characterizing RI , denote the numerator and denominator in the logarithmic term of (15) as $\text{Num}(B)$ and $\text{Den}(B)$. Let B_+^n and B_-^n ($B_+^n > B_-^n$) represent the roots of the quadratic equation in $\text{Num}(B)$ derived from adding and subtracting the radical in the quadratic formula, respectively. Let $B^r = (a_1 - r)/2b$ denote the root of $\text{Den}(B)$. B^r represents the "golden-rule" stock level prevalent in capital-based models that equates the marginal productivity of the biomass

stock (the biological rate of interest) with the financial rate of interest, i.e., $G'(B^r) = r$.

Assume that the intrinsic growth rate of biomass is greater than the discount rate, i.e., $a_1 - r > 0$. This appears reasonable for the study area over a wide range of circumstances (see table 1) and decreases the enumeration of possible cases. Given this assumption, application of Descartes' Rule of Signs (Albert, p. 171) to $\text{Num}(B)$ implies that B_+^n and B_-^n are either both positive real roots or a complex conjugate pair; B^r is clearly positive. When B_+^n and B_-^n are real, RI can be shown to have vertical asymptotes approaching positive infinity at B_+^n and B_-^n , and a vertical asymptote approaching negative infinity at B^r . Figure 1 shows how the configuration of RI depends on the magnitude of B^r relative to B_+^n and B_-^n .³

The position of RI in phase space depends critically on the magnitudes of the limiting marginal profitability of recovering the final unit of biomass (referred to hereafter as limiting marginal profitability)

$$(16) \quad \lim_{(R,B) \rightarrow (0,0)} \partial \pi(t) / \partial R = \alpha q p \bar{A} - c_0,$$

and on a_0 , which is directly related to the minimum viable biomass stock, \underline{B} by (3a). In figure 1a-c, a *ceteris paribus* increase in limiting mar-

ginal profitability drives both the leftward and rightward portions of RI upward. A *ceteris paribus* increase in \underline{B} also drives the rightward portion upward, but drives the leftward portion downward.

Steady-state solutions. Steady-state solutions of (11) occur at the intersections of the biomass and recovery zero-change isoclines. Figure 2 shows a phase diagram, associated with the RI depicted in figure 1b, depicting a three-steady-state configuration. Clearly, other three-steady-state configurations are possible if the RI 's in

³ When B_+^n and B_-^n are a complex conjugate pair, the rightward portion of RI is no longer defined, and the leftward portion is similar to that in figure 1a.

Table 1. Baseline Parameter Values

Symbol	Meaning	Units	Value
a_1	intrinsic annual growth rate of biomass	yr^{-1}	$(a_0 = 500)$ 0.158 $(a_0 = 5,000)$ 0.583
b	density dependence of biomass growth	$(\text{kg}/\text{ac})^{-1}\text{yr}^{-1}$	$(a_0 = 500)$ $6.5E-7$ $(a_0 = 5,000)$ $3.1E-6$
\bar{A}	max. annual areca nut production level	$\text{kg}/(1/6)\text{ac}/\text{yr}$	300
α	production parameter		0.00039
q	fraction of recovered biomass in greenleaf		0.9
p	unit return of areca nuts	Rs/kg	14.81
c_1	unit cost parameter		$(c_0 = 0.3)$ $1.3E-5$ $(c_0 = 1.7)$ $1.7E-4$
r	real annual discount rate		0.047

figures 1a,c are used. In addition, figure 2 bifurcates to a one-steady-state configuration if, for example, limiting marginal profitability is sufficiently large relative to other parameters to position the leftward portion of RI above BI . However, an analysis based on the three-steady-state configuration in figure 2 suffices to elucidate the general issues.

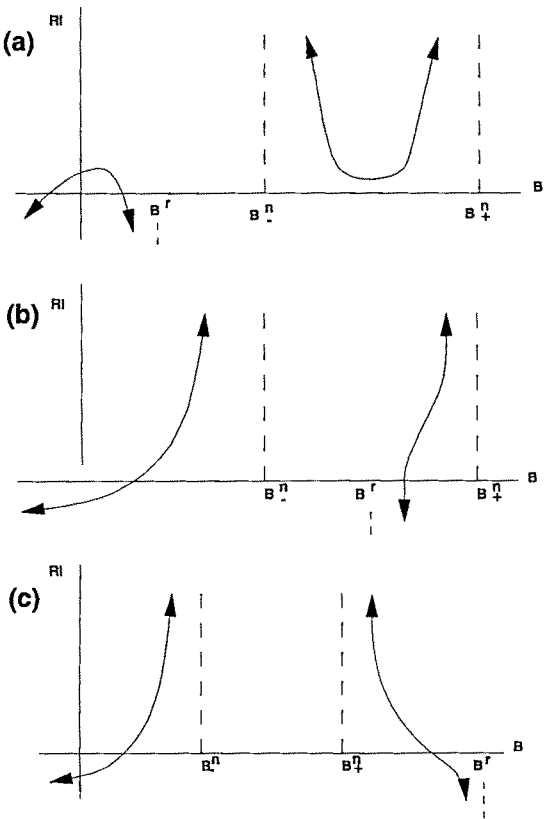

Figure 1. The recovery zero-change isocline, RI : (a) $B^r < B^- < B^+$; (b) $B^- < B^r < B^+$; (c) $B^- < B^+ < B^r$

Direction of motion. The arrows in figure 2 depict the direction of motion away from steady state. Since $\dot{B}'(R) < [0 \text{ by (11b)}]$, biomass densities tend to decrease over time for recovery rates above BI and increase for those below. Recovery rates can be shown [by signing $\dot{R}'(R)$ in the following intervals] to decrease for biomass levels to the right of the rightward portion of the recovery zero-change isocline; increase for biomass levels between the rightward and leftward portions; and decrease for biomass levels to the left of the leftward portion.

Local stability properties. Local stability properties of the steady states in figure 2 can be examined by linearizing system (11) in the neighborhood of each steady state. The Jacobian matrix of this linearized system is J with a characteristic polynomial

(17) $CP(E) = E^2 - Tr(J)E + Det(J) = 0,$

where $Tr(J) = \dot{R}'(R) + \dot{B}'(B)$ is the trace and $Det(J) = \dot{R}'(R)\dot{B}'(B) - \dot{B}'(R)\dot{R}'(B)$ is the determinant of J . $Det(J)$ can be shown to be negative for steady-state biomass stocks greater than the maximum sustained yield level, B_{msy} . This implies that $CP(E)$ has roots (eigenvalues) of opposite sign, which in turn indicates that a steady state occurring to the right of B_{msy} is a saddle-point equilibrium.

Alternatively, $Det(J)$ is indeterminate for steady-state stocks to the left of B_{msy} ; hence, stability properties cannot be guaranteed by this procedure short of numerical computation of the associated eigenvalues. However, stability properties can be deduced from the direction of motion of the system (as depicted by the arrows in fig. 2). Motion around the outer steady states (denoted as SS_L and SS_H) is consistent with a saddle-point equilibrium, whether or not SS_H is

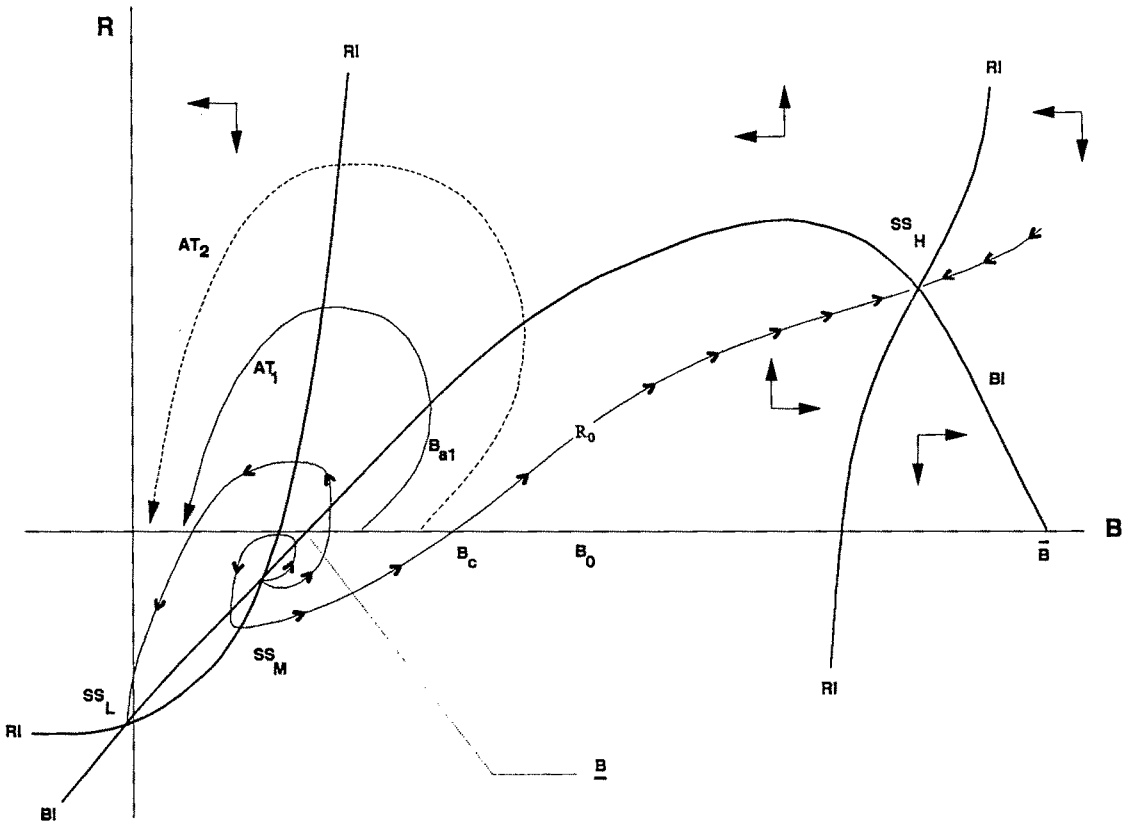

Figure 2. Phase diagram with three-steady-state configuration

to the right of B_{msy} . Motion around the middle-steady state, SS_M , is consistent with either an unstable focus (eigenvalues are a complex conjugate pair with positive real parts) or an unstable node (eigenvalues are positive real numbers).⁴ In either case, two convergent separatrices (arrowed trajectories) emanate from SS_M and asymptotically approach their respective outer steady states.

In figure 2 the optimal continuous recovery strategy [assuming that sufficient condition (13) is met] is to select initially the recovery rate $R(0) = R_0$ lying directly above $B(0) = B_0$ on the separatrix converging upward toward the positive-biomass steady state SS_H .⁵ The upward conver-

gent separatrix approaching SS_H is consistent with the nonnegativity restrictions on B and R for $B_0 \in [B_c, B_H]$, where B_c is the separatrix' largest biomass-axis intercept. The downward convergent separatrix approaching SS_H satisfies nonnegativity for $B_0 \in [B_H, \infty)$. Hence, the optimal continuous strategy is feasible for $B_0 \in [B_c, \infty)$.

Optimal Abandonment Strategy

The optimal abandonment strategy is selected from among paths satisfying (11) but veering away from steady state. These paths imply abandonment within a finite time, T , by crossing either the biomass axis (where there is no further economic incentive to recover biomass) or the recovery axis (where recovery necessarily ceases because the biomass is exhausted). The optimal path among these satisfies the free terminal-time transversality condition (10f) requiring that the Hamiltonian (9) must approach zero as t approaches T , and the nonnegativity restric-

⁴ Davidson and Harris (appendix a) rule out the possibility of closed cycles as optimal trajectories in optimal control problems with exponential discounting and one state variable and one costate variable.

⁵ In the case where the lower-biomass saddle point, B_L , is positive and satisfies the sufficient conditions, and both B_L and B_H are approachable from B_0 , the extramarginal analysis set out in Davidson and Harris may be used to select the convergent separatrix representing the optimal continuous policy.

tions on the terminal biomass level $B(T) = B_T$. The nonnegativity restrictions require the costate variable to approach a nonnegative limit (10g), and the product of the costate and state variables to approach zero (10h), as t approaches T . Condition (10h) implies one of the following three cases: (1) B_T is positive and $\lambda(T) = \lambda_T$ is zero; (2) Both B_T and λ_T are zero; or (3) B_T is zero and λ_T is positive.

Case 1. $B_T > 0$, $\lambda_T = 0$. The optimal levels of B_T and R_T must satisfy

$$(18a) \quad \lambda(T) = pA'(R_T) - C(B_T) = 0$$

$$(18b) \quad H(T) = pA(R_T) - C(B_T)R_T = 0,$$

where $\lambda(T)$ is derived from (10a). Condition (18a) requires marginal revenue of recovery, $pA'(R_T)$, to equal marginal cost, $C(B_T)$, at the optimal terminal recovery and biomass levels. Condition (18b) requires average revenue of recovery, $pA(R_T)/R_T$, to equal average cost, $C(B_T)$. Both conditions are met when marginal revenue equals average revenue. Given the concavity of $A(R)$, marginal revenue lies below average revenue for $R > 0$, hence equality occurs only when $R_T = 0$. Solving (18a) for optimal B_T when $R_T = 0$ yields

$$(19) \quad B_T = -(1/c_1) \ln(paq\bar{A}/c_0),$$

which is restricted to be positive in Case 1, implying that $paq\bar{A} < c_0$. The optimal terminal stock condition (19) requires that B_T increase (thereby promoting conservation of the stock) as the limiting marginal profitability of recovering the last unit of biomass (16) becomes increasingly negative.

In Case 1, the producer abandons the *soppinabetta* before foliage is completely exhausted because recovery is no longer economic. Abandonment results in eventual extinction if the stock is driven to a terminal level to the left of the minimum viable level (3a), i.e., $B_T < \underline{B}$. Setting $B_T < \underline{B}$ in (19) implies eventual extinction when limiting marginal recovery costs, c_0 , are less than a critical level that increases with the minimum viable stock,

$$(20) \quad c_0 < paq\bar{A} \exp(c_1 \underline{B}).$$

Alternatively, Cases 2 and 3 above both stipulate a priori that the optimal abandonment policy will result in extinction because B_T is set to zero. The difference between the two cases is in the optimal terminal recovery rate, R_T .

Case 2. $B_T = \lambda_T = 0$. Conditions (18a) and (18b) (evaluated at $B_T = 0$) continue to be relevant and require that marginal revenue equals average revenue at R_T ; hence, R_T continues to be identically zero. This is economically reasonable because specifying that $B_T = \lambda_T = 0$ imposes the restriction that the limiting marginal profitability of recovering the last unit equals zero [by (19)]. Hence, the terminal recovery rate is zero because the producer would have no economic incentive to harvest another unit even if it could be produced.

Case 3. $B_T = 0$, $\lambda_T > 0$. The optimal level of R_T must now satisfy

$$(21a) \quad \lambda(T) = pA'(R_T) - C(B_T = 0) > 0$$

$$(21b) \quad H(T) = pA(R_T) - C(B_T = 0)R_T + \lambda_T[G(B_T = 0) - R_T] = 0.$$

Substituting in (2), (4), (5) for $G(B)$, $A(R)$, $C(B)$, respectively, and λ_T from (10a), into (21b), yields after some manipulation,

$$(21c) \quad H(T) = p\bar{A} + c_0a_0 - p\bar{A} \exp(\alpha q R_T) [1 + \alpha q(a_0 + R_T)] = 0.$$

Condition (21c) is convex in R , and under the specifications of Case 3, has two roots of opposite sign. The positive root is the optimal terminal recovery level R_T . In contrast to Case 2, the optimal terminal recovery rate is positive because recovery remains profitable as biomass reaches extinction [$\lambda_T > 0$ implies that the limiting marginal profitability of recovering the last unit is positive].

Figure 2 shows the unique abandonment trajectory, AT_1 , associated with the optimal terminal pair of recovery rate and biomass stock in Case 1. Let the largest biomass level lying on AT_1 be denoted as B_{a1} . Then, the optimal abandonment strategy is feasible for initial biomass levels in the interval $B_0 \in [B_T, B_{a1}]$. The producer engages this strategy by initially selecting the unique recovery rate, R_0 , lying directly above the initial biomass level, B_0 , on AT_1 .

Optimal Recovery Strategies

Consider the problem of whether to select an optimal continuous strategy or an optimal abandonment strategy over the entire domain of initial biomass levels. Assume first that the feasible domains for each strategy do not overlap.

This occurs with optimal abandonment trajectory AT_1 in figure 2, which is drawn so that AT_1 does not lie anywhere above the upward convergent separatrix for $B > B_c$. Each strategy is the overall optimal strategy within its feasible domain, and the superiority of one over the other is not an issue.

Neither strategy is feasible for initial biomass levels in the intervals $B_0 \in (0, B_T)$ and $B_0 \in (B_{a1}, B_c)$. The only feasible choice from such initial stocks is among suboptimal abandonment trajectories that eventually intersect either the recovery axis (given relatively "large" initial recovery rates) or the biomass axis to the left of \underline{B} (given relatively "small" initial recovery rates) and thus result in eventual extinction. The choice among these trajectories must be made by computing the associated present values.

In summary, when the feasible domains of the optimal strategies do not overlap, the producer will select a continuous strategy leading to ecological balanced use if $B_0 \geq B_c$, or some type of abandonment strategy resulting in eventual extinction if $B_0 < B_c$.

Assume, alternatively, that the feasible domains of the optimal abandonment and continuous strategies overlap, thereby raising the issue of which strategy is superior in the overlapping interval. The optimal abandonment trajectory is now AT_2 (dashed path in fig. 2), which lies above the upward convergent separatrix for a small interval of $B_0 > B_c$. Cropper (proposition 1) shows in a generalized resource extraction model that, when $0 \leq B_T \leq \underline{B}$ (as for AT_2), a $B_0 > \underline{B}$ exists such that the optimal abandonment strategy is superior to the optimal continuous strategy and extinction is therefore optimal. Denote this critical initial stock as B_{cr} . Then, for $B_0 \leq B_{cr}$ an abandonment strategy is overall optimal, and for $B_0 > B_{cr}$ the optimal continuous strategy is overall optimal. The economic rationale is that growth is sufficiently slow for $B_0 < B_{cr}$ that it does not pay to build the stock up toward SS_H at the expense of foregoing the net benefits of driving the stock to extinction.

Simulated Areca Nut/*Soppinabetta* Dynamics

This section uses available case study information to generate numerical simulations of areca nut/*soppinabetta* dynamics in (11). The goal is to identify circumstances under which (a) a representative present-value-maximizing producer in the study area favors abandonment and even-

tual extinction over a continuous recovery strategy; and, hence, (b) granting ownership of the *soppinabetta* to areca nut producers is not a feasible strategy for preserving the resource.

The numerical simulations rely mainly on parameter values calculated from information on economic and ecological conditions provided in case studies of the region found in Gadgil, Gadgil, Hedge, and Bhoja Shetty; and Hulgol Service Cooperative Society. Table 1 summarizes the baseline parameter values derived below.

Areca nut yield function parameters. Gadgil reported an average annual yield, $A(R)$, of 2.56 tonnes per hectare [173.085 kg/(1/6)ac] with the application of an average annual recovery, R , of 6 tonnes per hectare (2,434.02 kg/ac). Our own consultations with area producers resulted in the following values: $\bar{A} = 300$ kg/(1/6)ac/yr, and $q = 0.9$ (the fraction of recovery in foliage). Inserting these values into areca nut yield function (4) gives

$$(22) \quad 173.085 = 300(1 - e^{-\alpha(.9)(2434.02)}),$$

which can be solved for $\alpha = 0.00039$.

Areca nut unit return and discount rate. Gadgil reported that the average annual areca nut yield of 2.56 tonnes per hectare [173.085/(1/6)ac] generated an annual income of approximately rupees 38,000 per hectare [Rs 2,564.1/(1/6)ac]. Hence, the unit return is calculated as $p = 2,564.1/173.085 = \text{Rs } 14.81/\text{kg}$. The assumed nominal discount rate, $r_{\text{nominal}} = 0.1$, is the annual fixed deposit rate offered by commercial banks (Dena Bank, interest rate schedule, 1987). The real rate, $r = 0.047$, is calculated by netting out the annual percentage inflation rate (5.3%) over the period 1986–87 (Quarterly Economic Report of the Indian Institute of Public Opinion).

Plant growth parameters. Gadgil reported an average standing biomass of 28 tonnes per hectare (11,336 kg/ac) in his study area compared to 400 tonnes per hectare (161,944 kg/ac) in a good moist deciduous forest. The annual productivity of the above two types of forest were 3 tonnes per hectare (1,214.58 kg/ac) and 20 tonnes per hectare (8,097.2 kg/ac), respectively. These values are inserted into $G(B)$ in (2) to form the following two simultaneous equations:

$$(23a) \quad 1,214.58 = -a_0 + a_1(11,336.1) \\ - b(11,336.1^2)$$

$$(23b) \quad 8,097.20 = -a_0 + a_1(161,944) \\ - b(161,944^2).$$

Applying Cramer's Rule to solve this system for a_1 and b in terms of a_0 yields

$$(24a) \quad a_1 = \frac{a_0(11,336.1^2 - 161,944^2) + (8097.2)(11,336.1^2) - (1214.58)(161,944^2)}{(161,944)(11,336.1^2) - (11,336.1)(161,944^2)}$$

$$(24b) \quad b = \frac{a_0(11,336.1 - 161,944) + (8,097.2)(11,336.12) - (1,214.58)(161,944)}{(161,944)(11,336.1^2) - (11,336.1)(161,944^2)},$$

where a_0 is discussed below.

Recovery and cultivation unit costs. A case study by the Hulgol Service Co-operative Society reported that an average of 42 laborer days per acre were employed annually to recover foliage biomass from the *soppinabetta*. This results in a total recovery cost of rupees 630 per acre when multiplied by the average payment per laborer day (Rs 15 per laborer) (obtained in our own consultations with producers). Assuming that this total recovery cost is associated with Gadgil's reported figures on the average annual recovery rate of 6 tonnes per hectare (2,434.02 kg/acre) at the average biomass level of 28 tonnes per hectare (11,336.1 kg/acre), the unit cost of recovery is calculated as rupees 0.26 per kilogram (630/2,434.02). Hence, one point on the unit cost curve is $C(B_1) = 0.26$ and $B_1 = 11,336.1$. Unit cost function (5) can be used to solve for c_1 in terms of c_0 at this point:

$$(25) \quad c_1 = -(1/11,336.1) \ln(0.26/c_0),$$

where c_0 is discussed below.

Parameters a_0 and c_0 . Recall that a_0 determines the minimum viable stock level, \underline{B} , in (3a), c_0 is the limiting marginal cost of harvesting the final unit of foliage biomass in (16), and that both parameters are critical in determining whether the optimal abandonment strategy derived in Case 1 above (the only case not specifying extinction a priori) results in extinction by (20).

Unfortunately, information was not found to calculate these key parameters. The best that can be done currently is to simulate system (11) over

wide intervals for a_0 and c_0 to determine a range of dynamic behavior. Hence, four simulations were run alternating between high and low values for each. Growth parameter a_0 was set so that the minimum viable stock, \underline{B} , alternated between a "low" of approximately 3,000 kilograms per acre and a "high" of 9,000 kilograms per acre. Cost parameter c_0 alternated between a "low" level (0.3 Rs/kg) not satisfying the ex-

inction condition (20) for Case 1 above, and a "high" level (1.70 Rs/kg) satisfying it.

Each simulation recalculated growth parameters a_1 (24a) and b (24b), and cost parameter c_1 (25) so that the growth (2) and unit cost (5) functions continued to run through their respective observed data points, thereby maintaining use of this information (table 1). Increasing a_0 under these conditions squeezes the biomass zero-change isocline inward so that the new curve has a larger maximum sustained yield at a smaller stock level, a larger minimum viable population level, and a smaller carrying capacity (fig. 3a). Increasing c_0 (from c_{01} to c_{02}) under these conditions causes the unit cost curve to pivot around the observed data point with unit costs lying above (below) the old curve for stocks smaller (larger) than the observed point (fig. 3b).

Simulation Results and Discussion

Figures 4a-d show the numerically generated phase diagrams associated with each simulation.⁶ The inset to figure 4c enlarges the portion containing the optimal abandonment trajectory in order to highlight its location relative to the optimal continuous recovery trajectory. Table 2 summarizes steady-state stock and recovery levels along with eigenvalues and sufficient conditions (12) and (13) calculated for each steady state. Because figure 4 and table 2 are fairly comprehensive, the paper forgoes discussion of each simulation separately in favor of a general discussion summarizing the impacts of alternat-

⁶ The phase diagrams were generated by the BDPHS subroutine of Dynamical Software, Dynamical Systems, Tucson AZ.

ing between high and low levels for c_0 and B under the previously stated conditions.

Three of the simulations (figs. 4a, b, d) produce the single positive saddle point variation of figure 2 wherein the leftward portion of the recovery isocline (RI) lies above the biomass isocline (BI). Alternatively, the high c_0 –low B simulation (fig. 4c) produces the three-steady-state configuration shown in figure 2. Two steady states are added because high c_0 positions RI further to the right [by decreasing limiting mar-

ginal profitability (16)] and low B positions BI further to the left. The middle steady state, SS_M , is an unstable focus. The higher-biomass steady state, SS_H , is the only approachable equilibrium meeting the nonnegativity conditions on B and R .

Table 2. Steady States, Stability, and Sufficient Conditions

	Low \underline{B}	High \underline{B}
low c_0	$(B^*, R^*) = (158380, 8276)$ Eigenvalues = $-.083, .130$ First principal minor = $-3.0E-5$ Second principal minor = .43	$(B^*, R^*) = (158060, 9688)$ Eigenvalues = $-.433, .480$ First principal minor = $-1.8E-5$ Second principal minor = .06
high c_0	$(B_H, R_H) = (85656, 8306)$ Eigenvalues = $-.042, .089$ First principal minor = $-3.0E-5$ Second principal minor = .43 $(B_M, R_M) = (1786, -219)$ Eigenvalues = $.024 \pm .30i$ $(B_L, R_L) = (-513945, -254190)$ Eigenvalues = $-.502, .549$ First principal minor = $-3.1E-35$ Second principal minor = $-2.7E80$	$(B^*, R^*) = (87282, 22280)$ Eigenvalues = $-.119, .167$ First principal minor = $-2.2E-7$ Second principal minor = $2.4E-5$

The saddle points in figures 4a, b, d, and SS_H in figure 4c all meet sufficient conditions (12) and (13). Hence, the upward convergent separatrix associated with each is the optimal continuous strategy for $B_0 \in [B_c, B_H]$, and the downward convergent separatrix is the same for $B_0 \in [B_H, \infty)$.⁷ Interestingly, the initial feasible biomass stock on the upward convergent separatrix, B_c , varies little with changes in either c_0 or \underline{B} . The intervals containing B_c ranged from (13868, 13869) for low c_0 /high \underline{B} (fig. 4b) to (16811, 16812) for high c_0 /low \underline{B} (fig. 4c).⁸ Moreover, the feasible domains of the optimal continuous strategy and the optimal abandonment strategy do not overlap in any of the simulations. Hence, each strategy is overall optimal in its feasible domain.

The major impacts of increasing c_0 , while holding \underline{B} constant at either a low or high level, are mostly felt in the equilibrium stock, B^* , and the optimal terminal stock, B_T , and recovery rate, R_T . For low c_0 (figs. 4a, b), B^* is to the right of the maximum sustained yield stock, B_{msy} , (thereby guaranteeing a saddle-point equilibrium), and is a large percentage of the carrying capacity, \bar{B} (67% for low \underline{B} and 88% for high \underline{B}). However, for high c_0 (figs. 4c, d), B^* is to the left of B_{msy} (calculated eigenvalues indicate

that B^* remains a saddle-point equilibrium), and is a much smaller percentage of \bar{B} (36% for low \underline{B} and 49% for high \underline{B}). The reason that B^* moves to the left is that increased c_0 causes the new unit cost curve to lie below the old curve for biomass levels to the right of the observed data point ($B = 11,336.1$). This decreases the recovery cost savings of maintaining the larger equilibrium stocks in figures 4a, b.

Consider now the impact of c_0 on the optimal terminal point (B_T, R_T). For low c_0 (figs. 4a, b), limiting marginal profitability (16) is positive, hence the simulations follow Case 3 above where $B_T = 0$ and $R_T > 0$. For high c_0 (figs. 4c, d), limiting marginal profitability (16) is negative, hence the simulations follow Case 1 above where $B_T > 0$ and $R_T = 0$.

The major impacts of increasing \underline{B} (while holding c_0 constant at either a high or low level) occur in the steady state recovery rate, R^* , and the largest biomass stock on the optimal abandonment trajectory, B_{a1} . When \underline{B} is low (figs. 4a, c), steady-state recovery rates are similar for low c_0 ($R^* = 8,276$ kg/ac/t) and high c_0 ($R^* = 8,306$ kg/ac/t). However, when \underline{B} is high (figs. 4b, d), steady-state recovery rates increase and are markedly different for low c_0 ($R^* = 9,688$ kg/ac/t) and high c_0 ($R^* = 22,280$ kg/ac/t). Steady-state recovery rates increase because the associated steady-state biomass levels are situated to the left of the far-right observed data point ($B_2 = 161,944$ kg/ac) and the biomass isocline shifts upward in this region (fig. 3a). This increase is exaggerated in figure 4d because the steady state is near the peak of BI .

Biomass level B_{a1} tracks \underline{B} closely in the four simulations. When \underline{B} is at its low level of approximately 3,000 kilograms per acre (figs. 4a, c), B_{a1} equals 2,974 kilograms per acre (low c_0)

⁷ The location of the upward convergent separatrix associated with (B_H, R_H) , for example, was approximated by fixing $B = B_H$ and repeatedly numerically solving (11) for iterated values of R_0 . The procedure stopped when consecutive recovery levels produced trajectories veering away from steady state in opposite directions. The convergent separatrix is sandwiched between these trajectories. Hence, although the trajectory emanating upward from SS_M in figure 4c appears to be a single trajectory eventually splitting into two branches, it is actually two trajectories beginning from slightly different initial conditions.

⁸ The interval of biomass levels around B_c is the biomass-axis intercepts of the trajectories bounding the convergent separatrix.

or 3,467 kilograms per acre (high c_0). For high $B = 9,000$ kilograms per acre, B_{a1} is 9,280 kilograms per acre (low c_0) or 9,160 kilograms per acre (high c_0).

Conclusion

What do the above results imply about the conditions under which private ownership by a representative areca nut producer preserves the *soppinabetta*? The key parameters determining whether the representative producer selects a continuous recovery strategy over an abandonment strategy when their associated feasible domains do not overlap are B_0 (the initial stock level) and B_c , (the stock initializing the optimal continuous recovery strategy). When $B_0 > B_c$, an optimal continuous recovery strategy leading to ecologically balanced use is overall optimal. In contrast, when $B_0 < B_c$, the producer selects the optimal abandonment strategy if $B_0 \in [B_T, B_{a1}]$, or a suboptimal abandonment strategy otherwise. The simulations, run for a wide range of growth and unit cost curves, produce relatively narrow ranges for B_c of approximately 13,868 kilograms per acre (fig. 4b) to 16,812 kilograms per acre (fig. 4c), and for B_{a1} of 3,467 (fig. 4a) to 9,280 (fig. 4b).

Suppose that the average foliage level reported by Gadgil is the stock that the representative producer, just granted property rights to the *soppinabetta*, initially faces, i.e., $B_0 = 11,336$ kilograms per acre. This initial level falls below the calculated range for B_c and above the calculated range for B_{a1} ; hence, the optimal continuous recovery strategy and the optimal abandonment strategy are both infeasible. Only suboptimal abandonment strategies, producing eventual extinction of the stock, are feasible from this initial stock level.

Privatization will not preserve the *soppinabetta* under these circumstances. However, the government could increase the prospects for preservation by imposing a pre-privatization period of regulated use designed to increase initial biomass levels under privatization beyond the calculated range for B_c . The length and efficacy of such a regulatory period depend on how far

the stock is allowed to drop under the current regime and whether it declines below the minimum viable level, B . Clearly, the government must move fast because Gadgil estimates that current average use will deplete the stock within a decade.

Impact Targets versus Discharge Standards in Agricultural Pollution Management

John B. Braden, Robert S. Larson, and Edwin E. Herricks

When attempting to protect fish in streams, sediment or erosion targets are inefficient. Use of a habitat suitability target reveals lower cost abatement measures because it accounts for pesticides as well as soil particles. In Lake Michigan case studies, the lower cost measures involve more crop diversity, less use of no-till, and changes on more acres than the solutions based on sediment discharges or erosion rates.

Key words: environmental policy, fish, nonpoint pollution, optimization, targets.

Protecting water quality has been avowed as a major objective of soil conservation programs (U.S. Department of Agriculture). Yet, controlling soil movement continues to be stressed in practice; an example is the Conservation Reserve Program's emphasis on highly erodible lands. The effectiveness of protecting water quality by stabilizing soil is an open question.

This paper quantifies the economic losses from the use of soil movement rather than water quality criteria for the attainment of an important water quality goal—protection of habitat for high-valued fish species. The estimates are based on a case study of Lake Michigan tributaries. The case study also indicates the differences in farming practices when habitat is protected by controlling soil movement alone versus managing both soil and pesticide pollution.

The analysis extends the methods used previously by Braden et al., Crowder and Young, Heimlich and Ogg, Milon, Park and Sawyer, and Park and Shabman. The common theme of those

studies is the linking of land management economics to off-site consequences. The usual aim has been to compare various policies for meeting specified levels of pollutant loads.

The present study goes beyond previous work by considering predicted impacts on fish habitat. The costs and management implications of actual environmental damages, as well as of emissions and pollutant loads, then can be assessed. These three performance measures conform to the policy targets defined by Nichols—emissions, exposure, and damages; however, his "damage" category implies economic evaluation of the impacts, while no such evaluation is attempted here. Insight into the inefficiencies introduced by inexact targets is important in evaluating whether to incur the additional costs of measuring and monitoring actual damages.

Economic Model

The economic model portrays a fully informed watershed planner. The planner's objective is to achieve environmental goals at least cost. Difficulties of attaching values to environmental impacts frequently lead to the use of such second-best cost-effectiveness criteria (Baumol and Oates).

The decision context involves stochastic risks of environmental impacts. The environmental consequences of interest depend in part on the severity and timing of weather events in relation to crop cover and chemical use. All of these factors can vary over a planning horizon. Under

Thanks without implication go from the authors to Roy Black and Wayne Whitman for help with the case studies and to two anonymous referees for suggestions that improved the exposition.

such circumstances, the planner's decision framework follows in spirit the models of Beavis and Walker and Lichtenberg and Zilberman. Let $C(x)$ be a primal cost function defined over choice variables in the vector x , $q(x, \varepsilon)$ be an environmental quality production function, ε be a stochastic disturbance term, Q be a target level of minimum environmental quality, and A be a measure of reliability (the probability of achieving Q). The cost-effectiveness decision is

$$(1) \quad J = \text{Min } C(x), \text{ s.t. } \Pr[q(x, \varepsilon) \leq Q] \geq A.$$

This framework anticipates that higher quality can be achieved only by sacrificing cost or reliability or both. Greater reliability presents similar tradeoffs.

The environmental quality and reliability targets in (1) may be difficult to measure and monitor. Contributing factors, such as emissions or pollutant loads reaching the stream, may provide alternative policy targets. Suppose that the function $q(\bullet)$ can be rewritten as

$$(2) \quad q = \hat{q}(x, h(\hat{x}), \varepsilon), \hat{x} \subset x, x \not\subset \hat{x},$$

where $h(\bullet)$ is an intermediate environmental quality indicator, such as emissions or pollutant loads. The planner then may consider the alternative policy:

$$(3) \quad J = \min C(x), \text{ s.t. } \Pr[h(\hat{x}) \leq H] \leq B,$$

where the intermediate objectives H and B are based on knowledge about the stochastic relationship between $h(\bullet)$ and final objectives Q and A .

For achieving Q and A , the management choices based on (3) will never be less costly than selections based on (1). Fewer choice variables (instruments) are relevant to the performance measures, and those measures are inexact proxies for the final objectives. The extent of the inefficiency and the nature of the management miscalculations are empirical questions.

Model Implementation

The empirical model has been described in detail by Braden, Herricks, and Larson; and Larson, Herricks, and Braden. It consists of a version of the Sediment Economics (SEDEC) model (Braden et al.; Bouzaher, Braden, and Johnson; Johnson et al.) that is extended to include (a) seasonality of sediment loads; (b) pesticide losses, toxicity, and concentrations; and (c) effects of

sediment and pesticides on the habitat requirements of selected fish species.

Briefly, pollutant transport submodels for sediment and pesticides relate farming practices to pollutant delivery to waterbodies. SEDEC places these relationships in a spatial optimization framework, permitting the planner to identify the optimal type and location of interventions to achieve particular goals.

The pollutant loads are translated into habitat quality and reliability through habitat suitability models (U.S. Fish and Wildlife Service). These models are calibrated for individual species, of which more than forty have been characterized. Habitat suitability indices (HSI) are unitless numbers ranging from zero (poor) to one (excellent). They capture the combined effects of relevant habitat parameters, such as temperature, substrate conditions, and concentrations of contaminants.

Timing is extremely important in determining the effects on fish of soil and farm chemicals washed into streams by storm events. Monte Carlo simulations based on historical weather records, planting dates, and chemical application practices are used to capture these stochastic factors. The simulation outputs are probability distributions of pollutant discharges and habitat impacts. The probability distributions identify the likelihood (reliability) of achieving any specific suitability index level with a particular watershed management scenario.

The mathematical expression for the implemented model is a modified and elaborated version of problem (1) above. In addition to the earlier notation, let counting index $j, j = 1, \dots, J$, refer to subwatersheds and index $i, i = 1, \dots, I^j$, denote all possible combinations of management practices on the land units within a particular subwatershed. Each i will be called a management path. Variable $x_{ij} \in [0, 1]$ is binary and represents a management path in subwatershed j . Because only one such path can be chosen in each subwatershed, $\sum_i x_{ij} = 1$ for all j . PC_{ij} is the probability of pesticide concentrations exceeding a particular suitability level Q^* ; PS_{ijg} is the probability of sediment suitability exceeding Q^* in season g ; and A is the target level of reliability. Variable a_j is area of subwatershed j and f_{ij} is the predicted median runoff from management path i of subwatershed j . The decision problem is:

$$(4a) \quad \text{Min } C(x) = \sum_{j=1}^J \sum_{i=1}^{I^j} c_{ij} x_{ij}$$

s.t.

$$(4b) \quad \frac{\sum_{j=1}^J \sum_{i=1}^{I'} PC_{ij} f_{ij} x_{ij}}{\sum_{j=1}^J \sum_{i=1}^{I'} f_{ij} x_{ij}} \geq A$$

$$(4c) \quad \frac{\sum_{j=1}^J \sum_{i=1}^{I'} PS_{ijg} a_{ij} x_{ij}}{\sum_{j=1}^J \sum_{i=1}^{I'} a_{ij} x_{ij}} \geq A \quad g = 1, \dots, G$$

$$(4d) \quad \sum_{i=1}^{I'} x_{ij} = 1 \quad j = 1, \dots, J$$

$$(4e) \quad x_{ij} = [0, 1].$$

Constraints (4b) and (4c) are weighted-average probabilities of exceeding the target suitability level for pesticides and sediment, respectively. Variables a_j and f_{ij} are weighting terms used to reflect the relative contribution of each subwatershed.

A solution to this problem reveals the management choices that will achieve specified habitat quality and reliability levels at least cost. Varying the constraints will show the trade-offs between cost, quality, and reliability. More important, the model can be modified to constrain emissions or pollutant loads. The resulting solutions can be run through the habitat simulations to reveal how close they come to protecting quality and reliability. Doing so reveals the efficiency losses due to the use of intermediate targets.

Different targets should be good substitutes for policy purposes if they are closely correlated (Nichols). In that case, management prescriptions optimal for one indicator should be nearly optimal (although possibly second-best) for the other indicator.

In the case of agricultural pollution and fish habitat, timing can cause critical differences between emissions, releases, and habitat suitability. The timing effects come through decay in pesticide toxicity and the seasonal patterns of rainfall, erosivity, crop conditions, and fish spawning requirements.

Another source of divergence between targets is oversimplification. Environmental damages are frequently the outcome of complex processes involving many factors. Targets based on a subset of the processes may miss some im-

portant contributing factors. For example, erosion rates and sediment loads may not effectively represent the fates of soluble pesticides.

The size of the losses due to the use of proxy targets is an empirical matter. Insights are developed in a case study of sport fish protection in tributaries to Lake Michigan.

Case Study

Active sport fisheries have been successfully developed in Lake Michigan over the past two decades with substantial economic benefits for the near-shore area. Chinook, coho, steelhead, and other salmonids are the most prized varieties.

The salmonid populations have been sustained and enhanced through extensive stocking. Natural spawning has been limited in many tributaries by nonpoint pollution from farmland and by channelization that eliminates habitat while enhancing drainage. These factors not only compel continued stocking, they also reduce the range of seasonal salmon migrations. The migrations are highly valued by individuals and communities near the lake who seek to lengthen and enhance the fish runs.

The model was applied to two agricultural subwatersheds in Berrien County, Michigan, along Lake Michigan's southeastern shore. The Pipestone Creek site drains to the St. Joseph River and on to Lake Michigan. The states of Michigan and Indiana are working together to extend the salmon runs in the St. Joseph River system. The river and its tributaries have been abundantly stocked with juvenile sport fish in recent years. Portions are classified as trout streams. However, the segment of Pipestone Creek chosen for study has been channelized and the silty substrate is poor for spawning and fry development. The 93 hectare (ha) study site contains gently sloping farmland with silty and loamy soils.

The Galien River (east branch) site is part of a smaller river system that also is classified for trout. The habitat conditions are good for salmonids with a meandering channel, cobble and gravel substrate, and pools interspersed with riffle segments. The study site contains 139 hectares of gently sloping farmland with sandy and loamy soils.

Data

Catchments and transects were defined from U.S. Geological Survey topographic maps. Manage-

ment units were identified from Soil Conservation Service (SCS) soil survey maps, plat maps, and Agricultural Stabilization and Conservation Service aerial photographs. Soils information, including productivity classifications, also came from soil surveys (U.S. Soil Conservation Service). Rainfall distributions were based on a fifty-seven-year record for nearby Eau Claire, Michigan. Basic stream data were compiled through fieldwork.

Coefficients for the Universal Soil Loss Equation (Wischmeier and Smith) and crop budgets, including pesticide application rates and assumptions about the timing of farming operations, were prepared by experts in the Michigan Cooperative Extensive Service and the SCS (J. Black, Dep. Agr. Econ., Michigan State University, personal communication 1988). Corn, grains, and soybeans are the most common farm crops in Berrien County, although orchards, vegetables, and vineyards also are present. The crop-cover (*C*) factors for the USLE were disaggregated for crop growth phases, and variability was introduced following Thomas, Snider, and Langdale. Twelve possible cropping systems were considered, consisting of combinations of two rotations—wheat-corn (3)-soybeans (WCCS) and alfalfa (3)-corn (2) (AAACC), three tillage methods—moldboard plowing, till-planting, and no-till, and two mechanical practices—vertical plowing and contour plowing. These options are typical of the area, and the rotations make use of similar pesticides. Three pesticides were selected for study: Atrazine, Furadan, and Bladex. Atrazine and Bladex use does not vary with tillage practices, while Furadan is used in fewer years when tillage is reduced. Assumed crop prices were \$60 per ton for alfalfa hay, \$2.25 per bushel for corn, \$5.40 per bushel for soybeans, and \$2.30 per bushel for wheat.

Chemical toxicity data for salmonids were obtained from Mayer and Ellersieck and incorporated into habitat relationships using the techniques developed by Herricks and Braga. Physical suitability relationships were adapted from existing HSI models (e.g., Raleigh et al.).

Analysis

The SEDEC model was used to determine the economically optimal management practices for meeting sediment targets. The consequences for fish habitat suitability of the practices that optimally control sediment were determined using

the extended model (without optimizing for suitability impacts). A similar approach was followed for erosion targets. The analysis also was performed in reverse—the optimal practices were determined with respect to suitability targets and the sedimentation and erosion consequences of those practices were traced. Finally, the sub-watershed suitability target was applied to all individual catchments to assess the consequences of imposing uniformity throughout the stream reach.

While any suitability, sedimentation, or erosion levels could be selected for analysis, levels of 0.5, 0.7, and 0.9 were chosen here. These cover average to very good suitability conditions, on the assumption that poor conditions are not relevant environmental targets.

Results

The results are summarized as cost frontiers relating the minimum losses in farming profits associated with attaining particular environmental targets. The cost estimates do not reflect differences in farmer risks that may accompany different management systems; they assume that watershed management can be highly selective; and they assume all farmers would settle for the minimum compensation.

Figure 1 shows the cost curves for the two study sites assuming the extreme habitat suitability targets of 0.5 and 0.9 and allowing reliability to vary. The costs are per hectare for comparison, although the costs are borne unevenly across management units as a result of the optimization.

The curves are quite different for the two sites, and this is attributable to the different background conditions. The Galien site is already highly suitable and reliable for salmonids, while Pipestone is not. Thus, the costs are greater for attaining high reliability levels at Pipestone.

The curves for the 0.5 suitability level extend to higher levels of reliability than do the 0.9 curves. This suggests that the best practices for usual weather circumstances (that dominate the suitability determination) are not the same as the best practices for extreme conditions (that dominate reliability). Furthermore, conservative farming practices alone cannot achieve high levels of suitability with high reliability. The dual extremes would require either land use changes more substantial than those considered here or supplementary measures within the stream channels.

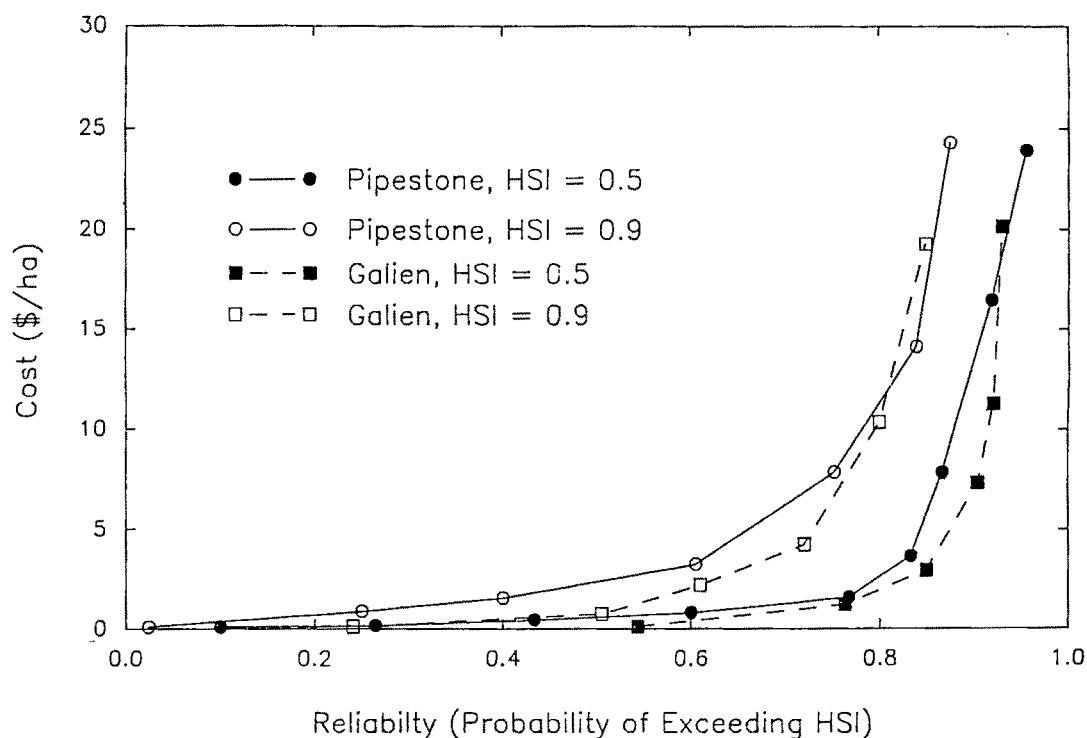

Figure 1. Minimum costs of achieving selected salmonid habitat suitabilities and reliabilities, Pipestone Creek and Galien River sites

The constraint on pesticide suitability is non-binding at low levels of reliability. The pesticide constraint does not become binding until rather high probabilities of exceeding the target suitability levels are reached, at which point the risk of excessive sediment accumulation is relatively low. (The reliability level at which pesticides become important varies inversely with the suitability level). These findings are consistent with the consensus among fisheries biologists that deteriorated substrate conditions are most responsible for the general degradation of fish populations in midwestern streams (e.g., Smith).

For the comparison of targets, figures 2 through 5 display the cost-suitability frontiers for (a) targeting directly on suitability; (b) constraining the total sediment load in the watershed; (c) constraining the sediment load from each catchment; and (d) constraining the soil erosion on each LMU, and the frontier from targeting directly on suitability. The 0.5 and 0.9 levels of suitability illustrate extremes.

The figures show that a sediment target reasonably approximates a habitat suitability target only over a limited range. The approximation grows worse as pesticides play a greater role in suitability determination, i.e., at higher levels of reliability where the pesticide suitability con-

straint is controlling. Because the critical pesticides are in solution, and because sediment runoff is not necessarily correlated with runoff volume or concentration, "targeting" sediment is a poor way to deal with pesticide effects.

Comparisons of the figures suggests that the range of reasonable approximation shrinks as the suitability target is raised. This shrinkage occurs because the pesticide constraints bind at lower reliability levels when suitability targets are higher.

The sediment and erosion target curves in figures 2 through 5 are not smooth because some strategies (e.g., alfalfa rotations) used to control soil movement also lower pesticides while others (e.g., no-till) can increase pesticide concentrations in runoff. Erosion and sedimentation targets take no account of the pesticide consequences and result in higher costs and greater or lesser reliability depending on the nature of the sediment control regime.

Management Implications

Optimal management scenarios for the HSI target are summarized in table 1, and corresponding results for the alternative targets appear in

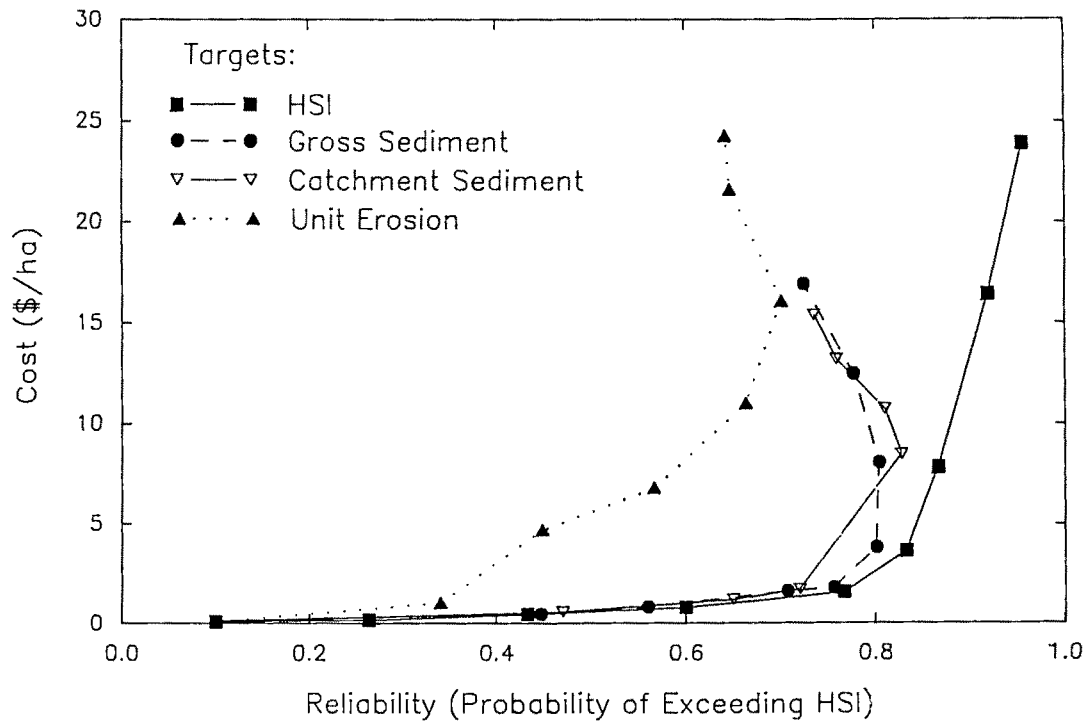

Figure 2. Cost of salmonid reliability with selected discharge targets and impacts, Pipestone Creek, HSI = 0.5

table 2. The selection of performance goals for table 2 was limited because some or all of the alternative targets could not achieve reliability of 0.8 at Pipestone with either the 0.5 or the 0.9 HSI, nor at Galien with 0.9 HSI.

In the baseline case, without habitat constraints, the WCCCS rotation and a combination

of tillage practices are implemented at both sites. As indicated in table 1, tightening the habitat constraint initially (the 0.5/.40 case) prompts greater use of no-till WCCCS. Requiring reliability of .80 causes a shift away from no-till WCCCS and toward the AACCA rotation. The greater availability and concentration of pesti-

cides with no-till accounts for this shift. Tightening the constraints also requires that changes be made in more management units and more acres.

For each site, the mechanical practices change little or not at all with different constraints because contour and vertical plowing perform very similarly on the long gentle slopes of the sites.

In comparing tables 1 and 2, the erosion and sediment targets generally lead to more acreage in the WCCCS rotation and more no-till. (An exception to the no-till result appears in the Galien 0.5/.80 case, but more use of conservation tillage with the HSI/Reliability target accounts for this apparent anomaly.) These results are as expected and are more pronounced, respectively, for gross sediment, catchment sediment, and erosion, that is, as the target becomes further removed from fish habitat.

An unexpected result, at least for the sediment targets, is that less area and fewer management units are involved in the solutions, albeit at higher overall costs. An interesting implication is that if administrative costs increase with the area and number of farms involved in abatement actions, the ostensible efficiency gains of using suitability/reliability targets could be offset.

Conclusions

This study suggests that protecting fish habitat can be quite distinct from reducing agricultural erosion or sediment discharges. Policies that address sediment or erosion effectively are less effective in protecting habitat, especially at high suitability and reliability levels. This is because soluble pesticides dominate extreme suitability and reliability conditions, and the correlation to sediment loads is not high. This result is not surprising because fish respond to multiple qualities of the stream channel. Single-dimensional policies will be effective only if the dimension chosen is highly correlated with overall suitability.

A specific policy concern involves no-till farming. No-till has been widely encouraged. At least in the cases studied here, this approach appears sound with respect to erosion and sedimentation. But the consequences for fish, and perhaps other wildlife, may be perverse; no-till sometimes involves greater use of pesticides, which are not as fully incorporated, while it also reduces runoff volume. Nonincorporation means that less water will move more chemicals. The

results point toward the desirability of no-till systems that better control pesticide releases.

Another policy issue involves the apparent desirability of heterogeneous cropping systems in a watershed. When suitability and reliability goals are high, changes in tillage and mechanical practices are inadequate. Crop changes are needed (unless stream channel measures are undertaken), and the changes entail more diversity. More diversity reduces the probability of any one chemical exerting influence in a particular weather event. Agricultural policies favoring the cultivation of fewer crops may hamper efforts to attain high quality stream fisheries in some areas.

The results suggest that less area and fewer farms are affected by targeting on sediment than on suitability. Thus, the apparent disadvantages of sediment targets may be less pronounced when administrative costs are considered.

Finally, the differences between targets in the costs of attaining particular quality/reliability goals are the potential gains from intensive water quality monitoring and measurement to fine tune abatement efforts. Intensive programs will undoubtedly be quite costly. There is apparently little to gain when quality/reliability goals are modest or when existing conditions are generally good. The emissions or exposure targets perform reasonably well. For fish habitat purposes, the gains from intensive programs probably warrant the costs only where they stand a good chance of greatly improving habitat for high-value species.

Tax Reform and Land-Using Sectors in the U.S. Economy: A General Equilibrium Analysis

Roy Boyd and David H. Newman

A computable general equilibrium model of the U.S. economy is used to assess the effects of the Tax Reform Act of 1986 on land-using sectors (forestry and three classes of agriculture). The model's components include twelve production sectors, six consumer groups, a balanced-budget government sector, and a zero surplus foreign sector. In relative terms, Tax Reform reduces total value added output in land-using sectors to a greater extent than other sectors in the economy. Experiments are also performed comparing partial and general equilibrium specifications of the economy and the impact of choice of input substitution elasticities.

Key words: general equilibrium, land use, tax policy, Tax Reform Act of 1986.

The sweeping changes brought about by the Tax Reform Act of 1986 (TRA '86) directly impacted more economic activities in the United States. Among land-using sectors, numerous tax provisions were changed, and these changes have been the subject for several partial equilibrium (PE) analyses. Income from timber harvests, for example, is no longer eligible for preferential capital gains treatment. Both Guertin and Rideout, and Greene and Kleunder calculated substantial private revenue losses due to higher costs when applying the new (higher) tax rates to a number of different land quality and ownership classes. Similarly, because farmers can no longer benefit from the Investment Tax Credit (ITC) or accelerated depreciation, producer profit-maximization models by Leblanc and Hrubovcak, and Boehlje and Carman predicted much higher capital costs for various crops in the future. A fundamental shortcoming of these studies is that they focus on a particular sector, separate from the rest of the economy. The effects of tax changes are economy-wide, and the resulting changes in factor and output prices can have profound effects on individual sectors, apart from their direct tax consequences.

Computable general equilibrium (CGE) models simulate the direct and indirect effects of proposed government tax legislation on a variety of industries and consumer income classes. Unfortunately, these models generally disaggregate manufacturing sectors while aggregating those sectors (such as agriculture and forestry) involved in the production of raw materials. Thus, understanding of the consequences of specific policies on land-based sectors is reduced. Our model closely follows Ballard et al.'s (BFSW) large CGE model of the U.S. economy in that their methods are used for constructing inputs into the model; however, our model is smaller and more specifically related to the policy concerns of this analysis. On the supply side of the economy, total U.S. production is divided into twelve production sectors which are used as inputs to create thirteen consumption commodities (as opposed to 19 and 15 in BFSW).

The purpose of this paper is to quantify the direct and indirect effects of the TRA '86 on land-using sectors using this CGE model of the U.S. economy. The analysis focuses on two important methodological and policy concerns. First, the results are compared using the same model inputs for both CGE and PE analyses. In this way, potential biases derived solely from the methodological approach can be discerned. Related to this analysis, the impact of substitution elasticities assumptions on these results are also examined. As a policy concern, we examine the equity effects of TRA '86 and its im-

impact on land-holding classes. The CGE model stratifies consumers by income class, allowing a more accurate portrayal of the direct equity impacts of major changes in the marginal rate structure, as well as the indirect equity effects of changes in relative consumer and factor prices (particularly that of land).

The theoretical, empirical, and tax components of the CGE model are discussed in the next section. Then the results of the policy runs are introduced, focusing primarily on the output, input, and price effects in the land-based sectors. From these results, we discuss the differences derived from equivalent PE runs as well as the sensitivity tests for substitution elasticities. The paper concludes with a discussion of the implications of TRA '86 for land-based sectors in the economy.

Specification of the CGE Model

Land-based production is divided into four sectors: forestry (i.e., timber crops used for further manufacturing production); AG-I, program crops (e.g., corn, wheat, cotton, etc.); AG-II, livestock (e.g., cattle and hogs, etc.); and AG-III, all other agricultural production (e.g., vegetables and fruit crops). Initially, competition for productive factors and simultaneous consumption demand shifts are ignored so that direct, tax induced, changes in these sectors can be measured. This allows the comparison of the PE results with previous work. Integrating these four sectors into the complete CGE model indicates the importance of general equilibrium considerations for land-based production.

Although the concepts involved in CGE models are straightforward, the model itself is fairly complex. In order to facilitate the model's presentation, we use the diagrams in figure 1, the equations in table 1, and the variable acronyms listed in the appendix. The overall equilibrium condition for each production sector j is

$$(1) \quad Y_j + GE_j + VM_j = \sum_j RAS_{jL} + GD_j + VX_j + INV_j.$$

Each of these components is now examined.

Supply

In figure 1, total sectoral output, Y_j , is the product of either a double- or triple-nested production function. First, material inputs enter as

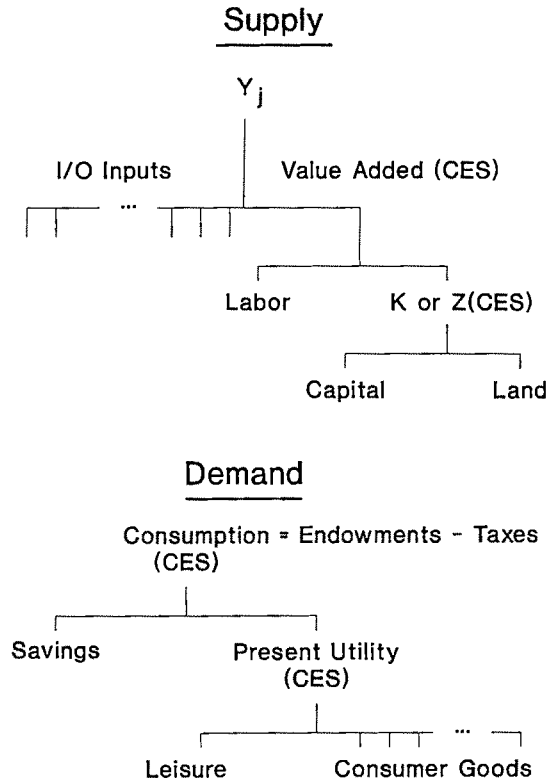

Figure 1. Schematic representation of supply and demand for the empirical model

Leontief, fixed-factor components of the national input-output matrix. The values added to production by labor and capital then enter as primary inputs into a nested constant elasticity of substitution (CES) production function. The substitution elasticity between these inputs can be set to any value between 0 and ∞ .

For the four sectors explicitly using land as an input, a nested variant of the value-added CES function is used. Input Z , which is a CES function of land and capital inputs, replaces K and, in effect, gives a CES production function within a CES production function. Nesting these functions, rather than using a simple three-factor CES value-added function, allows substitution elasticities to vary between the three primary inputs. Within such a setup, PE treatment of these four sectors is straightforward as primary inputs are provided at the (tax-inclusive) price and output demand does not shift. However, under general equilibrium, input prices may vary in response to economy-wide shifts and demand may shift in response to consumer income changes.

The use of land differs from previous CGE

models which included land. Hertel and Tsigas (1987, 1988) subdivided agriculture into seven crops in order to explain specific agricultural subsidies. Kokoski and Smith also used land as an input and were also interested in partial versus general equilibrium estimates. However, their model contains only a single agriculture sector. BFSW performed counterfactual experiments, such as consumption versus income taxes. They felt agriculture played a relatively minor role in such experiments and aggregated it into one sector, subsuming land into a broadly defined capital input.

Primary factor inputs are drawn from each of the ($c = 6$) income groups. Each income group supplies different quantities of land, labor, and capital (SD_c , SL_c , and SK_c), allowing the calculation of gains and losses accruing to specific resource owners. The total of these resources is either consumed as sectoral inputs or taxed away by the government [equations (2)–(7)]. Following BFSW, a unit of an input factor is that quantity which would produce \$1 worth of output per year, net of taxes. This accounting method does not allow the determination of input quantities by output sector, but it does allow the transfer of production units between sectors and deter-

mination of the resulting change in factor shares following a tax change.

Demand—Household

Each household's consumption is modeled as a triple-nested consumption function. At the first level, the consumer faces a CES tradeoff between present and future consumption (savings). Savings financed investment is assumed to equal total savings throughout the economy. Because this analysis is a static simulation, the savings/expenditure choice is not needed to account for dynamic economic growth. Rather, it is included because those taxes which discourage savings and investment have important consequences for output and relative prices in the land-based sectors.

At the second level, the consumer trade-off between leisure time and the goods and services bought from labor services is modeled with a CES nest. Finally, the ($i = 13$) goods and services, including savings, consumed by each household are derived from the ($j = 12$) sectoral outputs and taxed by the government in the form of excise taxes TC_i [equations (8)–(9)]. The

elasticity of substitution between any pair of these goods is assumed equal and, for most cases, is set to 1. Thus, the function collapses into a simple Cobb-Douglas utility function for each household, which is maximized subject to an income constraint [equations (9) and (15)].¹

Demand—Government

Given its initial endowments of goods as well as the taxes it collects, government demands goods and services to the extent that no surplus or deficit remains [equation (16)].² Government purchases should reflect some sensitivity to prices, so government demand for sectoral outputs, capital, and labor is modeled as a single-tiered, Cobb-Douglas consumption function. To preserve the correct incentive structure, consumers in each income class are taxed at their marginal tax rate, τ_c , and then receive the difference between collections using this rate and their average tax rate, PIT_c , as a lump-sum transfer, equation (12).

Foreign Trade

We assume that U.S. and foreign countries either cannot borrow from each other or that such borrowing is constant. Balance of trade thus remains constant [equation (17)] and the import and export elasticities of individual goods then may be varied by adjusting EM_j and FE_j [equation (14)]. Estimates for these elasticities were primarily taken from Stern, Francis, and Schumacher who indicate that "it may be reasonable to work with 'typical' demand elasticities that vary between . . . -0.5 and -2 for exports" (p. 14). We use elasticities close to their estimate of -.85 for agriculture, food, and raw materials such as timber and between -1.24 and -1.41 for other sectors. Finally, if equation (18) holds as an equality, the model is completely specified.

¹ The exact derived demand elasticity from this functional form is given in BFSW. Using their derivation, the share parameters used in this study and aggregating over all income classes, we obtain a derived demand elasticity for all agricultural goods of approximately -0.7. This elasticity is slightly lower than the -0.75 recently derived by Tarr and is the same as earlier estimates by Houthakker. Lower demand elasticities for individual agricultural commodities are presented in Hertel and Tsigas (1988).

² This assumption can easily be relaxed but would require an appropriate change on the consumption-investment equality or the balance of trade constraint.

Base Year Data

The methodology for manipulating the data for the empirical model is explained in BFSW. Data for the twelve production functions come from Caddy, Tarr, and BFSW. Capital receipts and taxes are computed from data provided by the U.S. Department of Commerce (1986), the U.S. Department of Agriculture (1985), Commerce Clearing House, the U.S. Department of Energy (1986a, b) and information provided in Hertel and Tsigas (1987). Factor shares for capital and labor in 1984 were obtained from recent spreadsheets by the Bureau of Economic Analysis. For the land-using sectors, capital was separated from labor by using the Forest Service's (preliminary) 1982 input-output matrix. Land was then separated from capital using spreadsheets from the ERS and the Forest Service.³ Because it would be difficult to derive substitution elasticities for this entire system of equations, these values are obtained from the existing literature. In order to get the sensitivity of the analysis to their values, the simulations were later run with altered elasticity values.

Corporate capital income receives double taxation; it is first taxed as corporate profits and the remaining distributed dividends then are taxed a second time through personal taxes. In order to calculate the total effective tax on capital, we used the method outlined in BFSW (reported in Boyd, table 2). Gross capital income for each industry was first derived, subtracting off property, franchise, and corporate income taxes. The fraction of capital income coming to individuals was then calculated along with the weighted average of the six income classes, τ . These values are then multiplied by capital earnings in the i th industry. Finally, each sector's tax rate is calculated, dividing net capital income by direct plus personal taxes in each sector. These values are shown in table 2. For highly incorporated sectors, such as manufacturing or food processing, double-taxation is more strongly felt. Less incorporated sectors, such as the agriculture and forestry sectors, generally escape the double tax.

In most cases, labor income was computed directly from the salaries and benefits for each production sector. For self-employed persons

³ The raw factor shares (table 3) were similar across all agricultural sectors. A counter intuitive finding was that field crops had the highest labor factor share. This anomaly may be explained by the high wage value of labor's marginal product in that sector and by the large amount of unreported earnings elsewhere in agriculture.

^a Base case relative prices are set to 1.000 for all sectors.

^b Change is the percentage change from the base case to the value after TAX-2.

(such as sole proprietor or farmer), labor income was imputed by taking the hourly wages of part-time employees in the same field and assigning them to the self-proprietors on a full-time basis (any excess was assigned to land or capital). Labor tax rates were obtained by subtracting from gross labor income, all employer contributions to social insurance and employee contributions to Social Security, unemployment insurance, public workman's compensation, and railroad retirement and dividing this value by net labor income. These rates range from 0.133 and 0.158 in manufacturing and food processing to

0.094, 0.094, 0.098, and 0.105 in the agricultural and forestry sectors. The agricultural rates are lower because many nonincorporated operations do not make social security and other labor payments (Boyd, table 3).

The land-using sectors' land taxes were computed by taking factor shares given by USDA, Economic Research Service (ERS) on capital use and extracting the land component from them. Land tax rates differ from capital tax rates in each sector by the relative magnitude of the subsidies and consumption allowances received by the two factors. The capital tax rates in the 3

^a Change is the percentage change from the base case to the value after TAX-2.

^b Price index is a Laspeyres price index based off of the pre-tax quantities.

^c "Utility" change quantify the combined effects of changes in purchasing power, leisure, and the cost of living.

agricultural sectors and forestry are 0.309, 0.372, 0.395, and 0.418, respectively (Boyd, table 1).

Other data needed came from the Bureau of Labor Statistics, which gave average expenditures for commodity consumption, factor earnings, and taxes paid by income class. The Survey of Current Business of the Department of Commerce (1986b) gave investment/saving, import/export, and government purchase data by sector. Finally, a 12×13 transfer matrix, based on the Department of Commerce's 1977 input-output table of the U.S. economy, described the transformation of sector outputs into commodity goods.

The Simulation Experiment

Initially, the PE simulation experiment is conducted for each of the four land-using sectors. Using the above data, output prices and production levels are solved within the context of a cost-minimization problem. The nested CES production functions are used to solve for these variables (Boyd, p. 7) under constant input prices and output demand. The appropriate input (or output) taxes are then added and the results are compared.

The general equilibrium simulation is more complex and was computed using Rutherford's solution algorithm. As a check of the model's consistency for the 1984 base year, we used a method analogous to that in BFSW's model. A major difference from their model is the inclusion of land as a separate factor of production in our model. As a final check, the base case model was run to determine if the simulation output matches the actual 1984 data. If it does, this solution becomes the benchmark for comparison with the output obtained after the model is run with tax changes.⁴

The policy analysis compares the simulation for the pre-TRA '86 base year of 1984 with the tax structure after the implementation of TRA '86. The taxes are added in two stages. First, only income tax changes affecting consumers (TAX-1) are added. These include changes to personal income and labor taxes (social security) which increase net wealth in all classes (though not by the same amount or percentage)

by lowering the marginal rate. These changes act similarly to a demand shifter for final consumption.

The greatest tax break from TRA '86 change goes to the upper and lower classes. The before and after marginal tax rates faced by the different consumer classes are shown in the first two columns of table 3. The U.S. tax system is only piecewise linear so that the marginal rates in table 3 apply only to the incremental tax dollars paid and not to the average rate paid by each income class (which is generally much lower). In the model, each income group is initially taxed at the relevant marginal rate and funds needed to keep average rates at their 1984 level are returned to them as lump sum payments.⁵

In the second stage (TAX-2), the changes used in TAX-1 are expanded by incorporating the reforms involving input taxes. TRA '86 removed corporate capital gains taxes and various capital recovery (depreciation) loopholes, as well as a general repeal of the investment tax credit (ITC). For most sectors, these changes are incorporated by using calculations from Fullerton, Gillett, and Mackie, as well as by taking values directly from Internal Revenue Service (IRS) tables and adding them into our calculation of the input tax for capital (table 2). For the agriculture sectors we used ERS spreadsheets, based on the IRS breakdowns. As shown in table 2, AG-I and AG-II are affected much more by the loss of the ITC and other tax breaks than is AG-III.⁶ These rate changes are in general agreement with previous work. Hansen and Bertelsen predicted capital price rises ranging from 15% to 32% for program crops and approximately 15% for livestock. No corresponding numbers have been calculated for the AG-III sector.

The differences between the agriculture sectors occur primarily because field crops and livestock require relatively large investments in buildings, storage facilities and heavy equipment. AG-III, on the other hand, produces largely nonstorable crops and relies more heavily on low cost labor for harvest and transport. Forestry was exempted from the provisions removing the ITC, but TRA '86 removed the special capital gains

⁵ The lump sum payments necessary to keep average taxes at their 1984 levels for the post-TRA '86 case are (in billions of dollars) for the lowest to the highest income classes, \$15.4, \$2.0, \$9.5, \$9.8, \$42.4, and \$193.1.

⁶ The formula for including tax changes for nonincorporated capital comes from BFSW (p. 67). The noncorporate ITC lowers the share of each industry's capital payments. The corporate tax is then allocated to each sector by its share and the ITCs used in each sector.

⁴ Although TRA '86 was explicitly designed to be revenue neutral, no revenue-neutral feature was built into our model. Instead, we use an unconstrained simulation because it is more realistic and it conveys valuable information on possible changes in the government deficit.

treatment status.⁷ Hence, in our model, we employ an output tax of 3.38% of the previous output value.

Results

Output Effects

Table 2 shows the expected value-added changes in the twelve production sectors from TAX-1 and TAX-2. While these changes appear small relative to sector size, the actual dollar value changes are substantial. As expected, output in most sectors increases from TAX-1 because of the increase in consumers net income and the resulting outward shift in demand. Only the manufacturing sector and several of the land-based sectors show output declines. Much of the manufacturing sector's output is used for investment, which declines as the relative return to savings falls as a result of the tax change.⁸ This result conforms with the findings of Fullerton, Gillett, and Mackie, who, with a CGE model with a fifty-year time horizon, concluded that the savings loss combined with reduced capital tax incentives chokes off manufacturing investment.

Output in land-using sectors declines because relative increases in the prices of more intensively used factors (capital and land) are greater than the increase in demand for their products. Prices, net of tax, for capital and land increase relative to labor because higher net wages induce more labor supply, making it cheaper for firms relative to the other factors (net, post-TRA '86, factor prices are, 0.9987 for labor, 0.9949 for capital, and 0.9557 for land while the base case rates for all factors are 1.0000).⁹ The biggest gainer from the large drop in the price of capital is the financial sector. As a result, consumption of commodities such as housing (which

strongly affects the forest sector) are expected to increase, because they are dependent on financial service costs.

Government revenue rises while overall output declines with the implementation of TAX-2. The forest sector, as well as several other sectors show relative declines as the loss of subsidies selectively impacts sectors. AG-I and AG-II are particularly hard hit by the loss of ITCs and other tax privileges as indicated by a loss of about \$127 million to landowners (table 3). High income groups bear the highest absolute losses, but simple calculations show that higher proportional losses accrue to lower and middle income landowners. The declines in AG-I and AG-II contradict Fullerton, Gillett, and Mackie, even though our CGE methodology is similar. The contradiction results from the use of different data sources. This study used ERS data which indicate that farmers have heavily utilized the ITC and various other tax benefits. This usage may be masked by more aggregate data sources.

The 1.4% decline in forest sector output is larger than any other sector, but the drop is much smaller than predicted by previous PE analyses (10% and higher). The previous studies did not allow for an overall decrease in the cost of land resulting from its general productivity decline. The loss of capital gains tax preferences leads to an annual increase of \$367 million (1984 \$) in taxes paid, which is the major cause of the drop in sectoral output. This loss is offset to some extent by the retention of ITCs and changes in factor input usage. Previous studies have ignored the change in factor prices and usage in calculating their much larger sector impacts.

Factor usage is set by the gross factor return faced by firms. Even though net capital price declines, the gross price faced by firms buying capital inputs rises relative to labor.¹⁰ Because forestry is relatively capital intensive (table 4), its costs increase relative to other, more labor-intensive sectors like manufacturing. Forestry firms thus shift to more labor-intensive management, rather than capital and land-using management patterns. In the process, they give up 0.39% of their land holdings and experience relatively larger declines in their capital and land factor shares compared with the decline in their labor factor share. This result, though consistent qualitatively with previous studies, is much smaller in magnitude than the large declines in

⁷ In most instances, a capital gain refers to the change in the price of an asset and preferential tax treatment would be modeled as a lower input tax. In forestry, preferential treatment was given to the harvested timber value. Because such gain reflects the value added by the production process itself, the removal of capital gains requires it to be modeled as an output tax.

⁸ Following Boskin, a savings elasticity of 0.4 was used for the empirical simulations. Because of conflicting evidence from Summers and Owen, values of 0.3 and 0.8 were used in the sensitivity analysis. Raising (lowering) the savings elasticity to 0.8 (0.3) caused inconsequential increases (decreases) in agricultural production and prices.

⁹ An aggregate leisure demand elasticity of -0.3 (Killingsworth) was used. In sensitivity tests, this elasticity was lowered to -0.5, which caused the supply of labor to increase slightly, causing the relative prices of land and agricultural goods to rise. These small changes point to the robustness of the model.

¹⁰ Changes in the gross price of capital facing firms can be calculated by adding the changes in net capital price to the changes in factor tax rates given in table. 3.

Table 4. Factor Shares in the Land-Using Sectors Occurring as a Result of Tax Reform Part-1 and Part-2

Factor	BASE*	Forestry TAX-1	TAX-2
		(%)	
Capital	34.2	34.4	33.3
Labor	15.2	15.2	15.1
Land	24.9	25.1	24.3
		AG-I	
Capital	18.8	18.9	19.3
Labor	13.7	13.7	13.7
Land	19.8	20.1	19.8
		AG-II	
Capital	13.5	13.5	13.4
Labor	10.1	10.1	10.1
Land	14.1	14.3	14.1
		AG-III	
Capital	17.1	17.1	16.7
Labor	12.0	11.9	11.9
Land	18.0	18.2	17.8

* Percentages sum to less than 100% because inputs from other sectors are included in the production function.

the productive forest land base predicted by the PE analyses.

Output declines also occur in AG-I and AG-II, which face increased tax payments of about \$640 million. The loss of ITCs is especially damaging because both sectors previously used them extensively. Productive land holdings increase by 0.08% and 0.007% as firms substitute land for capital. Surprisingly, AG-I actually increases its factor share for capital because the relative increase in its gross price is large enough to cause an increase in its total factor share, despite a decrease in the quantity of capital. AG-III, which prior to TRA '86 did not significantly use ITCs, is the only land-using sector showing positive gains in value added production with capital usage increasing and land usage decreasing.

Price Effects

TRA '86's effect on received prices, net of taxes, for sector outputs is consistent with the previous results. The *numéraire* for all prices in table 2 is the manufacturing sector price. Most sector prices drop relative to manufacturing because capital input costs in other sectors are less severely affected by the loss of ITCs and preferential capital gains tax rates.

Prices of forest sector products increase substantially relative to manufacturing. Increases in

the forest sector's operating costs and declines in output combine to increase the price of forest sector products. As a result, demand for imports from the foreign forest sector increases nearly 2%, from \$4.38 billion (1984 \$) to \$4.46 billion (1984 \$). Similarly, the two agricultural sectors exhibiting declining output also show rising prices. Because the overall cost of capital drops, the increases in agricultural prices are smaller than those found by Hansen and Bertelsen.

Partial Equilibrium Simulations

Because PE analyses assume that factors of production are infinitely elastic, overall factor price changes resulting from taxation are not allowed. In PE analyses capital price is fixed and known, while in a CGE model it is part of the solution. Thus, while some of the incidence of an increase in the capital tax falls on capital owners in a CGE model, all factor price increases are shifted forward in a PE analysis. For example, the PE analysis for the forest sector predicts a 3.4% increase in price and 3.1% decrease in output, while the CGE model predicts only a 1.7% increase in price and 1.4% decline output. Similar, yet smaller changes also occur for agriculture (compare the base case and PE columns in table 5).

The CGE and PE results differ for two reasons. One is the microeconomic effect that greater price increases from the supply shift lead to greater quantity declines along the downward-sloping demand curve. Second, a tax change affects demand as well as supply in a CGE model because all markets are connected. In this analysis, the demand for land-based goods shifts out from TRA '86 and further reduces the predicted drop in output.

Sensitivity Tests for Substitution Elasticities

A major concern in studies such as this is the need to use external sources for key components of the model, particularly substitution elasticities. In the agriculture literature, the estimation of input substitution elasticities has received considerable attention (e.g., Antle, Ball). However, these values have received relatively little attention in the forestry literature. Values as high as 2 to 3 have been used for the capital/labor (K/L) elasticity in timber production (Boyd and Daniels). These relatively large values were jus-

Table 5. Effect of Partial Equilibrium and Changing Substitution Elasticity Values in Land-Using Sectors on Output and Prices from TAX-2

Sector	Base Case	PE	Elasticities Used				
			Fixed Coeff.	Low-Level	Mid-Level	Cobb-Douglas	High-Level

Land	-0.50%	—	4.80%	0.33%	-0.56%	-1.50%	-1.81%

tified by the long production period and ample substitution possibilities for timber growers.

In this study, a value of 1.5 was used for the *K/L* elasticity and 1.0 for the capital/land (*K/D*) elasticity in forestry. In agriculture a value of 0.7 was used for the *K/L* elasticity in all three sectors and 0.3 for the *K/D* elasticity in AG-I and AG-III and 0.4 in AG-II because of its larger scale. To test the sensitivity of the results to elasticity choice, the model was rerun by varying the elasticities in the land-using sectors from 0, the fixed coefficients case, 1.0, the Cobb-Douglas case, and an extreme value of 1.5.

Results from these experiments are shown in table 4. Because, these elasticity changes have only slight impacts on the rest of the economy, only the land-using sectors are shown. Resource inputs remain in place in the fixed coefficients case, so firms in the sector are unable to respond to changing input prices. As in the PE test, output declines and prices increase substantially in all of the land-using sectors because firms retain relatively low-valued excess capital. The extra capital in these sectors substantially increases the net price of land, thus increasing its marginal product value. As the elasticity of substitution increases, the adverse effects of TRA '86 caused by the decreasing net price of capital are ameliorated as firms buy relatively inexpensive labor. Although output still declines in three of

the four sectors, both the output declines and price increases are smaller than in the base case. Net land prices decline as firms liquidate low-valued capital causing a decline in the relatively fixed land factor.¹¹

This exercise emphasizes that the expected impacts from a policy change such as TRA '86 will be strongly determined by the choice of model parameters. The more easily that sectors can substitute inputs, the smaller are the direct and indirect impacts on that sector. In the same manner, if inputs are sticky in a sector, the impacts of policy changes may exceed predictions. For example, in much of the country, forestry is a residual land use. If forestry becomes submarginal for production, the land will revert to natural cover with less economic value rather than shifting to other sectors. While this land may provide other amenity values for the economy, it is no longer included in the productive base of the economy. Because our model does not allow for land to leave the economy, the full effect of TRA '86 on land resources in the economy may be understated.

¹¹ Sensitivity tests were also conducted with respect to export demand elasticities. Because prices in most land-based sectors rise, increasing the elasticity of export demand leads to a further decline in exports and production. Because international trade is only indirectly affected by the policy changes examined here, the changes in output are modest (less than 0.05% of land-based production).

Implications for Consumer Equity

The changes in net expenditures by income level after TRA '86 are shown in table 2. The restructuring of marginal tax brackets (*TAX-1*) has a positive direct effect on all income groups. High and low income classes are the biggest gainers because they receive the largest bracket reductions. TRA '86 also has indirect effects on consumer equity. Increases in capital taxation lower the price of both capital and land.¹² Landowners are hurt as a group, and taxpayers in lower income brackets are hurt the most (percentage-wise) because they own a substantial amount of land. By raising capital taxes differentially across sectors, the relative prices of consumer goods change.

Because each income class consumes commodities in differing proportions, we constructed a Laspeyres price index for each group, with the pre-tax quantities serving as quantity weights for all income groups. As shown in table 3, declining agricultural and housing costs give progressively lower relative benefits as the income class increases. Household "utility" changes, which quantify the combined effects of changes in purchasing power, available leisure, and the cost of living are also readily extracted from the MPS/GE computer output. These changes are also highly correlated with changes in income (table 3). Overall, the income and household "utility" effects are dominated by the direct effect due to changes in marginal bracket rates. When *TAX-2* is brought in, the income and utility gains from *TAX-1* to high income classes are severely dampened by the fall in capital prices and the resulting capital factor losses.

Conclusion

This study uses CGE techniques to assess the economy-wide changes expected from the TRA '86. The analysis focuses on the land-using sectors of the economy but considers changes in other sectors as well. Overall, the sectoral impacts are relatively small when compared to sector size, but the tax changes bring about important changes in land management. These land use impacts are often difficult to discern using

PE techniques because macro-policies such as TRA '86 change the relative prices of factor inputs and outputs causing more complicated production changes.

The forestry sector results of this study provide for interesting comparisons with previous PE analyses. Those studies (Guertin and Rideout, Greene and Kleunder) showed that forest management was adversely affected by TRA '86 and predicted large declines in timber production. Our analysis confirms these results in that the forest sector is relatively the hardest hit sector in the economy with output declining substantially. However, the decline is much less than has been shown previously because several general equilibrium considerations dampen TRA '86's effects. First, output prices increase because of increases in the relative cost of forest production and because of income-induced increases in the demand for sector outputs. Second, relatively cheaper labor substitutes for capital in the forest production process as firms move to more extensive land management practices. Finally, land is substituted for capital used in production as the value of capital gains decrease. In total, these market responses to the new economic situation cause a much smaller decline in the forest sector than has been projected.

The agriculture sector is also negatively affected by TRA '86. Because the loss of ITCs and other benefits is felt more strongly by the program crops sector, this part of the agriculture economy is the most strongly affected. The loss also affects the livestock sector through the rising price of feed grains. The vegetable and other crop category (AG-III), which is the least reliant on the ITCs, is the least affected by TRA '86, because it can absorb released low-cost capital and land to increase its production.

This general equilibrium analysis offers several general conclusions. First, unlike PE models of sectors such as forestry and agriculture, CGE analysis accounts for the finite resources and thereby avoids overestimating the effects of tax reform on sectoral output. Second, because CGE analysis provides a consistent accounting network, important changes in the demand for outputs are not overlooked. Third, when sectors within a CGE model have different inputs or receive different tax treatments (e.g., agriculture), valuable information will be lost if they are not disaggregated. Finally, a CGE model can explicitly explore equity issues by accounting for the costs and revenues occurring to different consumers.

¹² This result occurs because land is not free to move. Because the demand for agriculture goods declines and total agriculture revenue falls, the price of land falls relative to the price of labor.

Consumer's Surplus Revisited

J. S. Shonkwiler

A technique for approximating welfare measures using knowledge of the Marshallian demand relation is developed and compared numerically to the true measures and other approximations. The technique does not rely on the solution of differential equations and is easily illustrated graphically. The technique should be useful as a pedagogic device and applicable in empirical work when derivation of the indirect utility function is burdensome.

Key words: compensating variation, consumer's surplus, Marshallian demand, welfare.

In 1976 R. D. Willig proposed a method to approximate compensating and equivalent variations when only the Marshallian demand relation was known. In fact, three distinct (though related) measures were introduced, each of which required information on the Marshallian consumer's surplus, the income elasticity, and the initial income level. One of these measures provided exact calculation of compensating variation, but only when the income elasticity was constant over the price change.

J. A. Hausman, five years later, correctly pointed out that approximation is unnecessary because a differential equation technique can be used to recover a local indirect utility function. Unfortunately, solution of the differential equation occasioned by a complicated Marshallian demand equation may be tedious in light of the relatively simple approximation proposed by Willig. Of course, it is tempting to suggest that empirical analyses should employ theoretically plausible demand specifications whose parameters can be related to a well-defined indirect utility function. Then neither approach need be adopted. This line of reasoning, however, ignores the occasional need for analytical expediency and the possibility that theoretically based systems may require modifications to better address complexities (see Pollack and Wales).

This reexamination provides an alternative technique for approximating welfare changes (compensating variation in particular) using a Marshallian demand relation. The technique is

about as easy to apply as Willig's rule-of-thumb measure and appears to be applicable over a comparable range of values of the income elasticity and consumer's surplus relative to income. Further, the approximation method has a distinct pedagogic attraction in terms of relating changes in income to changes in utility. The development proceeds by first discussing Willig's approximation and then developing the alternative technique. Some numerical comparisons then are provided.

The Two Techniques

Willig's rule of thumb measure for a single price change is

$$(1) \quad CV \approx A + \frac{\eta A^2}{2m^0},$$

where CV and A are compensating variation and consumer's surplus, η is the income elasticity and m^0 is the initial income level. The rule of thumb is derived from the successive solution of two differential equations and the application of a Taylor-series approximation. The derivation is explicitly developed in Willig's paper and will not be repeated here. Unfortunately, his approach is rather sterile and is not easy to explain graphically.

Some authors (e.g., Just, Hueth, and Schmitz) have tried to motivate the measure in (1) with an argument along the following lines:

Consider that $CV \approx A + 1/2 \Delta q \Delta p$, where p represents the price and q represents the quantity of a good. In figure 1, A is the area bounded by $p^0 abp'$ and CV is the area bounded by $p^0 acp'$. Δq is the line segment bc and $\Delta p = p' - p^0$. It

Valuable comments by R. D. Emerson, J. W. Milon, and two anonymous reviewers are acknowledged by the author.

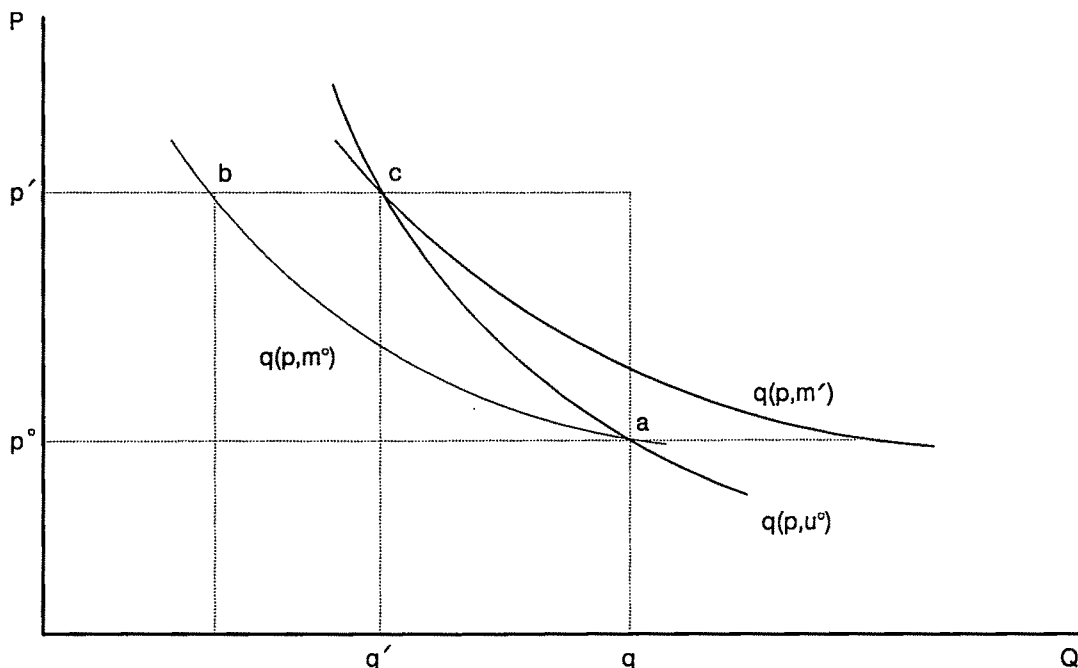

Figure 1. Compensated and uncompensated demand functions

is apparent that $\Delta q = q(p', m') - q(p', m^0)$. Then,

$$\lim_{m' \rightarrow m^0} \Delta q = \lim_{m' \rightarrow m^0} \frac{[q(p', m') - q(p', m^0)]}{m' - m^0} \cdot (m' - m^0),$$

or $dq = \lim_{\Delta m \rightarrow 0} \partial q / \partial m \Delta m$, so that

$$CV \approx A + 1/2 \frac{\partial q}{\partial m} \Delta m \Delta p.$$

Now, recognizing that $\eta = \partial q / \partial m \cdot m / q$, we have

$$(2) \quad CV \approx A + 1/2 \eta \frac{\Delta m}{m} q \Delta p.$$

At this point the argument is that for small Δp , both Δm and $q \Delta p$ may be approximated by A , hence the expression in (1). The problem with the final conclusion is that it is not entirely clear what Δm is measuring. If Δm provides a limit for CV , why not set Δm equal to CV and solve (2) for CV ? Alternatively, A underapproximates both CV and $q \Delta p$, suggesting (1) would not be nearly as good an approximation as it really is. Perhaps the unsatisfactory nature of the explanation for expression (1) should not be surprising because it is an improper simplification of

an approximation which originates from a much different approach.

The alternative technique for approximating CV has the advantages of not being based on differential equations and is easily developed graphically. In figure 1 note that the compensated demand curve approximately bisects the area between the two Marshallian demand curves when considering the price change from p^0 to p' . Recall that for a compensated demand function, $q(p, u^0)$, and an expenditure function, $C(p, u^0)$, having as arguments the reference level of utility, u^0 ,

$$(3) \quad \begin{aligned} CV &= \int_{p^0}^{p'} q(p, u^0) dp = \int_{p^0}^{p'} \frac{\partial C(p, u^0)}{\partial p} dp \\ &= C(p', u^0) - C(p^0, u^0) \\ &= m' - m^0 = \Delta m, \end{aligned}$$

and define two measures of consumer's surplus by

$$(4) \quad \begin{aligned} A &= \int_{p^0}^{p'} q(p, m^0) dp \text{ and} \\ A' &= \int_{p^0}^{p'} q(p, m') dp. \end{aligned}$$

This leads to the approximation

$$(5) \quad CV \approx A + 1/2(A' - A) = A + 1/2 \Delta A,$$

and using the definitions in (3) and (4) yields the expression

$$(6) \quad \Delta A = \int_{p^0}^{p'} [q(p, m^0 + \Delta m) - q(p, m^0)] dp.$$

Expression (6) illustrates that if the limits of integration are fixed, changes in income shift the Marshallian demand curve and thus lead to changes in consumer's surplus. Because m is a constant in the integration, standard results on differentiating under the integral sign (e.g., Woods, pp 141–42.) can be used such that

$$(7) \quad \lim_{\Delta m \rightarrow 0} \frac{\Delta A}{\Delta m} = \int_{p^0}^{p'} \frac{\partial q(p, m^0)}{\partial m} dp = \frac{\partial A}{\partial m}.$$

In terms of differentials this gives

$$(8) \quad CV \approx A + 1/2 \frac{\partial A}{\partial m} dm.$$

However, evaluation of (8) using information based solely on the Marshallian demand relation cannot be performed because dm , or its discrete approximation, Δm , is unknown. Yet, Δm is precisely the income change necessary to remain on the original compensated demand curve after the price change. Therefore, $\Delta m = CV$ and (8) can be solved in terms of CV to yield

$$(9) \quad CV \approx \frac{A}{1 - 1/2 \partial A / \partial m} = dS.$$

This approximation (dS) of compensated variation [approximate equivalent variation can be obtained by reversing the sign on the second term in the denominator on the right-hand side of (9)] follows directly from geometric arguments and does not require the solution of differential equations. As such, it is a more intuitive device for relating welfare measures to consumer's surplus. Interestingly, the dS measure has the same form in the linear specification as a measure suggested for expression (2) when Δm is equated to CV so that expression (2) becomes

$$(10) \quad \frac{A}{1 - 1/2 \frac{\partial q}{\partial m} (p' - p^0)}.$$

dS as an Approximation

The error bounds on the true value of CV for the dS approach can be shown to coincide ex-

actly with those presented by Willig. This is accomplished by writing expression (5) as an equality which depends on an unknown proportion ρ ,

$$(11) \quad CV = A + \rho \Delta A.$$

Some algebra leads to the result that

$$(12) \quad \rho = \frac{\Delta m - A}{\Delta A}.$$

Both Δm and ΔA depend on the unknown level of compensating income, m' . Willig provides bounds for m' , and these could be used to provide bounds for ρ , if desired. The discrete change form for dS becomes

$$(13) \quad CV = \frac{A}{1 - \rho \frac{\Delta A}{\Delta m}},$$

which identically equals Δm when expression (12) is substituted into (13). As would be expected, the bounds on CV are identical between the two approaches because $\Delta m = m' - m^0$ and the bounds on m' are used to provide the bounds on CV .

Two sources of error must be recognized in evaluating the approximation in (9): (a) the use of $1/2$ instead of the unknown proportion, denoted by ρ , and (b) the use of the derivative $\partial A / \partial m$ in place of the difference quotient $\Delta A / \Delta m$. As a consequence of these approximations, it appears that the dS measure does not perform well when the magnitude of compensating variation is large relative to income and the price elasticity and income elasticity are inelastic and elastic, respectively.

The results for a two good linear demand specification illustrate the effects of these factors on the approximation error. In table 1, various price, ϵ , and income elasticities of demand and corresponding levels of compensating variation are evaluated for a 100% price change at an initial income level of $m = 100$. Both W [Willig's rule-of-thumb measure from expression (1)] and dS are calculated from the initial price-quantity equilibrium. When the budget share, s , is large and when demand is price inelastic and income elastic, dS substantially overestimates CV . However, as the budget share and hence CV drops, the magnitude of the errors also declines.

These relationships are more systematically developed in table 2 for a log-linear demand function. Again, a 100% price change and an

-.545	.455	.44	35.87	34.33	35.56	.87

^a Where (1) is the price elasticity of demand, (2) is the income elasticity of demand, (3) is the budget share, (4) is actual compensating variation, (5) is Willig's rule-of-thumb measure, (6) is the alternative approximation of CV, and (7) is the percentage error of (6) relative to (4). Note the quantities in columns (1), (2), (3), (5) and (6) are calculated at the initial price and income levels. Initial income level is $m = 100$.

initial income level $m = 100$ are used. The results suggest that dS provides a reasonably accurate measure of CV provided calculated dS is not close to m , especially under price inelastic and income elastic demands.

The approximation value of dS is also illustrated for the quasi-homothetic demand specification. The budget share model that results from Deaton and Muellbauer's quasi-homothetic cost function is used as an example because A becomes a nonlinear function of m when the demand relation is written as a function of q . True CV can be calculated directly from the indirect utility function given in their article. The bounds on CV provided by Willig (W bounds) are also calculated. The results in table 3 again document that the dS measure provides reasonably good approximations to compensated variation only using information based on the Marshallian demand relation.

As a final consideration, deadweight loss (DWL) is measured by recognizing that q' in figure 1 can be estimated rather accurately in the approach developed. This occurs when the cal-

culated measure $m^\circ + dS$ is substituted for m° in the Marshallian demand relation. Then the approximate DWL becomes

$$(14) \quad DWL \approx dS - q(p', m^\circ + dS)\Delta p.$$

An example of the approximation's value in the context of the gasoline demand model presented by Hausman is considered. The calculated dS value is \$37.14 (versus a true CV of \$37.17) and approximate DWL is \$2.86 (versus a true value of \$2.88). This approach reinforces the view that knowledge of Marshallian demands can lead to good estimates of welfare measures.

Concluding Remarks

As long as the magnitude of the calculated measure dS is small relative to the initial income level the approximation performs on par with or better than Willig's rule-of-thumb measure. The degree of accuracy is also influenced by the relative magnitudes of the price and income elasticities of demand. Finally, it should be noted

The Calculation of Research Benefits with Linear and Nonlinear Specifications of Demand and Supply Functions

Jan P. Voon and Geoff W. Edwards

This paper provides a comparison of research benefits for linear and nonlinear constant elasticity (NLCE) specifications of supply and demand with a pivotal supply shift framework. The comparison allows for a sensitivity test of results to different values for demand and supply elasticity. The main finding is that the values of the gross annual research benefits calculated for the NLCE specification are larger than those calculated for the linear specification with price-elastic supply but are smaller with price-inelastic supply. The analysis suggests that the use of an NLCE specification and a pivotal shift due to research is usually preferable to use of a linear supply curve with pivotal shift.

Key words: demand-supply specifications, elasticities, model comparison, research benefits.

Market models have been used extensively for measuring the level and the distribution of benefits from R&D-induced supply shifts. In those models the supply and demand schedules were assumed to be either linear or nonlinear with constant elasticity (NLCE), and the R&D-induced supply shifts were assumed to be either parallel or nonparallel. Comparisons of research benefits occurring with linear parallel and linear nonparallel shifts in supply were provided by Lindner and Jarrett, Rose, Wise and Fell, and Norton and Davis. Comparisons of research benefits for linear and nonlinear specifications of the demand and supply curves have not been provided. The main aim in this paper is to provide such comparisons.

Both the linear and the NLCE frameworks have frequently been used in empirical work on evaluation of research benefits. The use of either framework involves little or no computational difficulty and appears practical for most empirical analyses. The NLCE pivotal supply shift framework has been adopted by Peterson; Ayer and Schuh; Akino and Hayami; Flores-Moya, Evenson, and Hayami; Nagy and Furtan; Wise; and Zentner and Peterson, among others. The

linear pivotal supply shift framework can be found in Lindner and Jarrett; Rose; McLean; Wise; and Norton, Ganoza, and Pomareda. Comparison of research benefits for linear and NLCE frameworks provides an understanding of the differences in results caused by model specification. This understanding is important in choosing between frameworks for estimating economic benefits from research and in interpreting results. The key point is that if a particular model specification is a better description of reality, then use of the alternative model specification can cause overestimation (or underestimation) of returns to research.

Comparison of the measured economic benefits from research using linear and NLCE supply curves requires specification of the type of supply shift resulting from research. This is not a straightforward task. No NLCE counterpart exists for some specifications of shifts in linear supply curves. The best example of this is the parallel shift in a linear supply curve, a specification used by several researchers (e.g., Rose, Edwards and Freebairn). Researchers using NLCE supply curves, on the other hand, have not used parallel shifts in supply due to research. This may be the result of an absence of analytical techniques for specifying a parallel shift of the NLCE supply curve and the function of

Jan P. Voon and Geoff W. Edwards are, respectively, a graduate student and a senior lecturer at LaTrobe University, Australia.

the new supply curve because NLCE supply curves always pass through the origin.

Because our aim is to compare estimated research benefits with linear and NLCE supply curves, it is important to formulate the analysis so that other factors affecting the size of research benefits, including the nature of the supply shift, are identical for the linear and NLCE cases. In order to do this, our approach confines the comparison to estimates of research benefits resulting from corresponding pivotal shifts in linear and NLCE supply curves. Because NLCE supply curves always pass through the origin, the pivotal shift for these curves is always about the origin.¹ For the linear case, however, the intercept is a function of the elasticity of supply. For supply elasticity greater than unity, the linear supply curves pivot on the positive price axis. For supply elasticity equal to unity, the linear supply curves pivot on the origin. For supply elasticity smaller than unity, the linear supply curves pivot on the negative price axis. The effects of the use of different values for the elasticity of supply on the size and distribution of research benefits are examined in this paper.

Research Benefits for Linear and Nonlinear Pivotal Supply Shifts

In this section, we outline the procedures used for comparing the level and the distribution of research benefits using linear and nonlinear constant elasticity specifications of the demand and supply curves. For comparison, we fix the following conditions [fig. 1(a) and 1(b)]: the supply shifts are pivotal for both cases; shifts in supply due to research, measured vertically as cost reductions at the initial equilibria, are identical ($A - D$) for the two cases; price (P_0) is identical for the two cases at the initial equilibrium, as is quantity (Q_0); and price elasticities of demand are identical for the two cases at the initial equilibrium, as are price elasticities of supply.

The general functional form for linear and NLCE demand and supply curves may be represented by $Q = f(P)$. When solving $Q = f(P)$ for P and Q , the notation $P = f^{-1}(Q)$ is used. That is, f^{-1} is the function inverse to f . The linear inverse demand curve, in an algebraic form,

¹ The power function of the nonlinear supply curve specified by Miller, Rosenblatt, and Hushak can pass through other points on the price axis, but this particular functional form is computationally difficult and is not practical for empirical purposes (e.g., a numerical calculation of producer surplus).

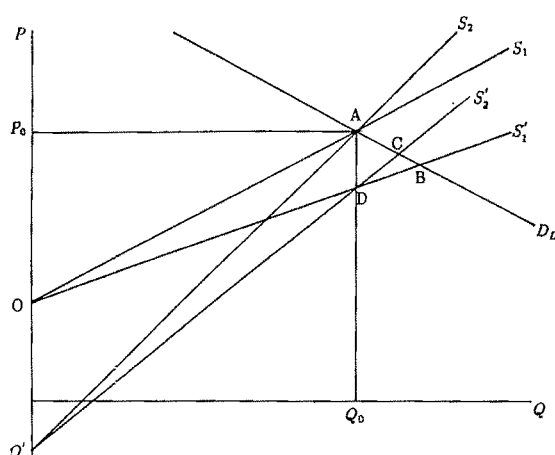

Figure 1(a). Effect of research with linear demand and supply curves

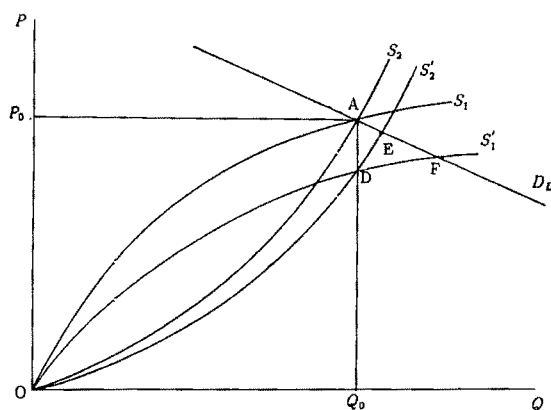

Figure 1(b). Effect of research with nonlinear constant elasticity demand and supply curves

is represented by $P = a - \alpha Q$, where a is a positive constant and α is the slope of the demand curve. Note that $\alpha = P/\eta Q$, where η denotes the own price elasticity of demand at the initial equilibrium. The linear inverse supply curve in the absence of research is represented by $P = b + \beta Q$, where b is a constant term and β is the slope of the supply curve. Again, $\beta = P/eQ$, where e is the own-price elasticity of supply at the initial equilibrium. The linear supply curve with research is denoted by $P' = b + \beta' Q'$, where β' is the slope of the 'with research' supply curve. Note that $\beta' = P(1/e - k)/Q$, where k [$k = AD/P_0$, as illustrated in figure 1(a) and 1(b)] represents the proportionate vertical shift in the supply curve ($0 < k < 1$).

The constant elasticity demand curve is represented by $P = AQ^{-\sigma}$, where A is a positive constant and σ represents the price flexibility of demand ($\sigma = 1/\eta$). The constant elasticity supply curve without research is $P = BQ^\gamma$, where B is a positive constant and γ is the price flexibility of supply ($\gamma = 1/e$) and the constant elasticity supply curve with research is $P' = (1 - k)BQ^\gamma$. The equilibrium price and quantity without the supply shift are P_0 and Q_0 .

Comparison of the gross annual research benefits (GARB) is performed for area OAB (or area $O'AC$) in figure 1(a) and area OAE (or area OAF) in figure 1(b).² The distribution of research benefits between producers and consumers with the linear and NLCE specifications is also compared.

Four combinations of the linear and NLCE demand and supply curves are identified. These are case 1: linear demand and supply curves ($D_L S_L$), case 2: NLCE demand and linear supply curves ($D_N S_L$), case 3: linear demand and NLCE supply curves ($D_L S_N$), and case 4: NLCE demand and supply curves ($D_N S_N$).

Let TS ($TS = GARB$) be the change in total economic surplus, CS be the change in consumer surplus, PS be the change in producer surplus, and subscripts 1, 2, 3, and 4 denote cases 1, 2, 3, and 4, respectively.³ The formula for calculating the level and the distribution of research benefits for case 1 [fig. 1(a)] is expressed as follows:

$$(1) \quad TS_1 = 1/2kP_0Q_1,$$

$$(2) \quad CS_1 = 1/2(P_0 - P_1)(Q_0 + Q_1),$$

² Consider first the linear case as shown in figure 1(a). For $e < 1$, the gross annual research benefit equals area $O'AC$ and for $e > 1$, the gross annual research benefit equals area OAB . Note that area OAB is bigger than area $O'AC$ by area CBD . For identical cost reductions, the values of the gross annual research benefits are little affected by changes in supply elasticity (since area CBD is very small) notwithstanding that, for $e < 1$, the linear supply curve passes through the fourth quadrant negative euclidean space. Now consider the NLCE case as shown in figure 1(b). For $e < 1$, the gross annual research benefit is represented by area OAE and for $e > 1$, the gross annual research benefit is represented by area OAF . NLCE supply curve takes a convex shape for $e < 1$ and a concave shape for $e > 1$.

³ The advantages and limitations of consumer and producer surplus measures are common to the linear and NLCE specifications that we are considering. Consumer surplus measures are widely used for analyzing welfare effects of price changes for agricultural products. This is generally regarded as appropriate, largely because income effects caused by price changes are likely to be small since consumers spend a very small fraction of their income on a particular food item (Bigman and Shalit). Producer surplus, also used widely in welfare analysis, is open to more serious questioning. Use of producer surplus is most clearly appropriate when rents accrue to a single-fixed factor, all other factors being in perfectly elastic supply (Mishan).

$$(3) \quad PS_1 = TS_1 - CS_1.$$

The "with research" equilibrium point for case 1 can be determined using the alternative formulas developed in this paper:⁴

$$(4) \quad P_1 = P_0[1 - ke/(e + \eta - ke\eta)],$$

$$(5) \quad Q_1 = Q_0[1 + ke\eta/(e + \eta - ke\eta)].$$

The formula for calculating research benefits with NLCE demand and supply (case 4) is expressed as

$$(6) \quad TS_4 = \int_0^{Q_0} S(dQ) - \int_0^{Q_0} S'(dQ) + \int_{Q_0}^{Q_1} D(dQ) - \int_{Q_0}^{Q_1} S'(dQ),$$

$$(7) \quad CS_4 = \int_{P_1}^{P_0} D(dP),$$

$$(8) \quad PS_4 = TS_4 - CS_4,$$

where $Q_1 = \exp(-\ln(1 - k)/(\sigma + \gamma))$ and $P_1 = (Q_1)^{-\sigma}$.

Similarly, changes in research benefits for the intermediate cases (i.e., cases 2 and 3) can be calculated using the above approaches.

Results

For illustrative purposes, the initial equilibrium prices and quantities were set at unity for each of the four cases, k was set at 0.1 (so the absolute shift is 0.1 P_0), and a range of demand and supply elasticities was used for comparison.

The size of $GARB$ and the calculated distribution of research benefits for case 2 ($D_N S_L$) are

⁴ Past models (Norton, Ganoza, and Pomareda; Rose) used the equations of Pinstrup-Andersen, Ruiz de Londoño, and Hoover (where $P_1 = P_0[1 - ke/(e + \eta)]$ and $Q_1 = Q_0[1 + ke\eta/(e + \eta)]$) for deriving the post-innovation (or "with research") equilibrium point [i.e., point B or C in fig. 1(a)], but these equations, as pointed out by Rose, are strictly correct only if the supply shift is parallel. For the linear pivotal supply shift model, the actual equations for determining the "with research" equilibrium point have been developed in this paper [i.e., equations (4) and (5)]. When research benefits calculated using the past approach were recalculated using the actual approach (using the parameter values assumed in tables 1 and 2 of this note), the values of $GARB$ were observed to be only marginally higher. The difference was found to be approximately 0%–3% with demand and supply elasticities in the range 0.1 and 5.0. A larger difference, however, is found in the calculated distributions of research benefits. For instance, recalculations showed that consumers' share of research benefits calculated from the past approach is smaller than those calculated from the actual approach by 10%–30% with larger values of η and e . Further details are available from the authors.

similar to those for case 1 ($D_L S_L$) for each combination of η and e , while the size of $GARB$ and the calculated distribution of research benefits for case 3 ($D_L S_N$) correspond closely to those for case 4 ($D_N S_N$). That is, for the marginal changes under consideration, the choice between the linear and nonlinear specifications of demand does not have a significant influence on price of the commodity "with research." It, therefore, has little influence on the size or distribution of $GARB$. Hence, for comparison, the results for cases 1 and 3 are taken (see table 1). The results for cases 2 and 4 are excluded from table 1 because the size and distribution of research benefits for case 2 is similar to that for case 1, while the size and distribution of research benefits for case 4 approximate that for case 3.

For supply elasticities less than about unity, the values of $GARB$ calculated for case 1 ($D_L S_L$) are higher than those calculated for case 3 ($D_L S_N$). For elasticities of supply greater than about unity, however, the values of $GARB$ are larger for case 3 than case 1. The magnitudes of the differences in $GARB$ for these two cases are larger the smaller the values for the supply elasticities (e.g., a difference of about 142% for $e = 0.25$ and about

16% for $e = 0.75$)⁵ (see table 2). The differences in $GARB$ are very small when the price elasticity of supply approaches unity.

For each of the four cases, the values of $GARB$ are insensitive to the value of the price elasticity of demand. The values of $GARB$ calculated using the $D_L S_L$ and $D_N S_L$ specifications (cases 1 and 2) are not sensitive to the choice of supply elasticity. However, the values of $GARB$ calculated using the $D_L S_N$ and $D_N S_N$ specifications (cases 3 and 4) are extremely sensitive to changes in supply elasticity. The explanation for this is as follows: for $e < 1$, the NLCE supply curves slope upwards at an increasing rate [see S_2 and S'_2 in fig. 1(b)], whereas for $e > 1$, the NLCE supply curves slope upwards but at a decreasing rate [see S_1 and S'_1 in fig. 1(b)]. Given an identical size of cost reduction at the initial equilibrium, the "with research" and the "without research" supply curves for $e < 1$ lie closer together (i.e., the mean vertical distance between the two supply curves S_2 and S'_2 is smaller), resulting in smaller values of $GARB$ relative to the linear

⁵ This is for $|\eta| = 1$. The pattern is similar for other values of $|\eta|$.

^a Major finding from table 1, using $\eta = -1$.

supply curves. The "with research" and the "without research" supply curves for $e > 1$ lie further from each other (i.e., the mean vertical distance between the two supply curves S_1 and S'_1 is greater), resulting in larger values of *GARB* relative to the linear supply curves.

Consumers' benefits from research are similar for each of the four cases. The significant difference in *GARB* between cases 1 and 2 on the one hand and cases 3 and 4 on the other reflect differences in benefits to producers. Producers can lose for each of the four cases when the demand for a commodity is price inelastic (i.e., $|\eta| < 1$), and with nonlinear supply (cases 3 and 4) producers gain from research only when $|\eta| > 1$.⁶ This contrasts with a linear parallel shift in supply when producers always gain (unless demand is perfectly inelastic). For each of the four cases, producers' gains from research increase (or losses decrease) with increases in η and fall with increases in e .

Concluding Comments

The major finding reported in this note is that the values of *GARB* calculated using the linear pivotal supply shift model (cases 1 and 2) are substantially larger than those calculated using the constant elasticity pivotal supply shift model

(cases 3 and 4) when the price elasticity of supply for the commodity is significantly lower than unity. However, when the elasticity of commodity supply is greater than one, the values of *GARB* calculated using the linear supply shift framework are considerably smaller than those calculated using the constant elasticity supply shift framework. An important implication of this finding is as follows: if the constant elasticity specification is a better description of reality, the linear pivotal supply shift model for evaluating research benefits leads to marked overestimation of research benefits when the commodity supply is inelastic but to considerable underestimation when supply is elastic.

It is debatable whether the real-world situation corresponds more closely to constant elasticity or to constant slope. In our view, commodity supply curves in agriculture are more likely to take the constant elasticity form. Both short-run and the long-run supply for many rural commodities have often been reported in the inelastic range (less than unity) (e.g., Vincent, Powell, and Dixon; Tweeten). With inelastic supply at the initial equilibrium, a linear supply curve passes through the negative fourth quadrant. An extrapolation of the linear inelastic commodity supply curve to the negative fourth quadrant (i.e., production of the commodity at undefined negative prices) is unrealistic. This problem is avoided by the use of constant elasticity supply curves; these curves pass through the origin. Our analysis, therefore, leads us to the view that the use of a nonlinear, constant elasticity specification of the supply curve and a pivotal shift due to research is usually preferable to use of a linear supply curve with pivotal shift.

Dairy Farm Efficiency Measurement Using Stochastic Frontiers and Neoclassical Duality

Boris E. Bravo-Ureta and Laszlo Rieger

This paper presents a stochastic efficiency decomposition model based on Kopp and Diewert's deterministic methodology. The stochastic model is used to analyze technical, economic, and allocative efficiency for a sample of New England dairy farms. The results suggest that mean economic efficiency for the farmers in the sample is about 70% and that, on average, there is little difference between technical (83.0%) and allocative (84.6%) efficiency. Analyses of the relationship between efficiency and four socioeconomic variables—farm size, education, extension, and experience—reveal that, despite some statistically significant associations, efficiency levels are not markedly affected by these variables.

Key words: economic, technical, and allocative efficiency; milk production; stochastic frontiers.

Efficiency measurement has received considerable attention from both theoretical and applied economists. From a theoretical point of view, there has been a spirited exchange about the relative importance of the various components of firm efficiency (Leibenstein 1966, 1978; Co-manor and Leibenstein; Stigler). From an applied perspective, measuring efficiency is important because this is the first step in a process that might lead to substantial resource savings. These resource savings have important implications for both policy formulation and firm management.

In the policy arena, there is a continuing controversy regarding the connection between farm size, efficiency, and the structure of production agriculture (e.g., Hall and LeVeen). For individual farms, gains in efficiency are particularly important in periods of financial stress similar to that experienced in U.S. agriculture in the 1980s. Efficient farms are more likely to generate higher incomes and thus stand a better chance of surviving and prospering.

The current interest in efficiency measurement finds its origin in a pioneering paper published by M. J. Farrell over thirty years ago. The approach proposed by Farrell distinguishes between technical and allocative efficiency where the former refers to the ability of producing a given level of output with a minimum quantity of inputs, given technology; the latter refers to the choice of the optimal input proportions given relative prices. Economic or total efficiency is the product of technical and allocative efficiency. Farrell's model, which is known as a deterministic nonparametric frontier (Forsund, Lovell, and Schmidt), attributes any deviation from the frontier to inefficiency and imposes no functional form on the data. Several extensions of Farrell's deterministic model have been made by Aigner and Chu, Timmer, Afriat, Richmond, Schmidt (1976), and Greene, among others.

A deficiency characterizing all deterministic frontier models is their sensitivity to extreme observations. A more recent approach for measuring efficiency, which seeks to ameliorate the extreme observation problem, is the stochastic frontier model developed by Aigner, Lovell, and Schmidt, and by Meeusen and van den Broeck. The stochastic frontier model assumes an error term with two additive components—a symmetric component which accounts for pure random factors, and a one-sided component which captures the effects of inefficiency relative to the

stochastic frontier. A recent extension by Jon-drow et al. has solved the previous inability of deriving individual firm efficiency measures from stochastic frontiers.

Farrell's model allows the computation of allocative, technical and, hence, of economic efficiency, but this computation is restricted to a technology exhibiting constant returns to scale. Recent work by Kopp and Diewert, Akridge, Kumbhakar, and Schmidt and Lovell has led to alternative formulations of parametric models which relax the linear homogeneity restriction while enabling the calculation of the various efficiency indexes.¹ In spite of these methodological developments, efficiency studies dealing with agriculture, in general, and U.S. milk production, in particular, have focused primarily on technical efficiency.

This paper contributes to the literature on firm-level efficiency measurement by extending Kopp and Diewert's decomposition technique from a deterministic to a stochastic model. This stochastic formulation yields technical, economic, and allocative efficiency measures that are free from distortions, stemming from statistical noise, inherent in deterministic models. In addition, the model makes possible a comprehensive efficiency analysis relying only on the econometric estimation of a production frontier, which is helpful because the firm-level price data required to estimate dual (cost or profit) models are often unavailable or inadequate (Quiggin and Bui-Lan). As far as we know, this is the only study that analyzes technical, economic, and allocative inefficiency besides the work by Taylor, Drummond, and Gomes for a sample of Brazilian farmers. The latter paper, however, utilized a deterministic model and, consequently, the resulting efficiency measures are sensitive to outliers.

The stochastic efficiency decomposition model is applied to a sample of New England dairy farms in order to quantify technical, allocative, and economic efficiency levels. The results show that focusing only on technical efficiency, as the applied studies of dairy farm efficiency have done (e.g., Bravo-Ureta, Grisley and Mascarenhas, Quiroga and Elterich, and Tauer and Belbase) considerably understates the potential gains from improvements in overall performance. An eval-

uation is made also of the relationships between inefficiency and farmers' socioeconomic characteristics. Efficiency in dairy production is important because technological innovations (e.g., bovine somatotropin, or bST), the seemingly chronic oversupply of dairy products, and attempts to reduce fiscal outlays for agricultural programs suggest that the trend toward fewer milk producers is likely to continue. During this period of adjustment, efficiency will be a key determinant of dairy farm survival.

Analytical Framework

Following Kopp and Diewert, we begin by assuming that the production frontier is given by

$$(1) \quad Q = g(X_a),$$

where Q is output, and X_a is a vector of variable inputs. The technically efficient input vector (X_t) for a given level of output (\bar{Q}) is derived by solving simultaneously equation (1) and the input ratios $X_1/X_i = k_i (i > 1)$, where k_i is the ratio of observed inputs X_1 and X_i at output \bar{Q} .²

Assuming that the production frontier is self-dual (e.g., Cobb-Douglas), then the corresponding cost frontier, derived analytically, can be written in general form as

$$(2) \quad C = h(P, Q),$$

where C is the minimum cost associated with the production of output Q , and P is a vector of input prices.³ Applying Shephard's lemma, we obtain

$$(3) \quad \frac{\partial C}{\partial P_i} = X_i(P, Q),$$

which is the system of minimum cost input demand equations. Substituting a firm's input prices and output quantity into the demand system in equation (3), we obtain the economically efficient input vector (X_e). The X_t and X_e vectors can be used to compute the cost of the technically efficient ($X_t'P$) and the economically efficient ($X_e'P$) input combinations associated with the firm's observed output. In addition, the cost of the firm's actual operating input combination

² For a homothetic production function, this solution essentially corresponds to the point where the efficient isoquant for \bar{Q} intersects the isocline $X_1/X_i = k_i$.

³ The method developed by Kopp and Diewert can also be implemented by estimating a cost frontier which need not be self-dual (e.g., translog). However, given the data available to us, we follow the primal route and use a self-dual function.

¹ The models developed by Akridge, Kumbhakar, and by Schmidt and Lovell require the joint estimation of the production frontier and the first-order conditions for profit maximization or cost minimization. Therefore, the high data requirements of these models preclude their consideration in this paper.

is given by $X_a'P$. These three cost measures can now be used to compute technical (TE) and economic (EE) efficiency indexes as follows:

$$(4) \quad TE = (X_i'P)/(X_a'P),$$

$$(5) \quad EE = (X_e'P)/(X_a'P).$$

Finally, allocative efficiency (AE), derived from equations (4) and (5), is given by

$$(6) \quad AE = (EE)/(TE) = (X_e'P)/(X_i'P).$$

Kopp and Diewert's decomposition approach is based on a deterministic frontier which imposes the limiting assumption that any deviation from the frontier is the result of inefficiency; hence, the resulting inefficiency measures are biased (Schmidt, 1985-86). To avoid this problem, we estimate a stochastic production frontier model and use the approach introduced by Jondrow et al. to purge the purely random error from the efficiency component.

To illustrate how the random error is purged, consider the stochastic production frontier,

$$(7) \quad Q = f(X_a) + \epsilon,$$

where

$$(8) \quad \epsilon = v - u$$

is the composed error term (Aigner, Lovell, and Schmidt; Meeusen and van den Broeck). The two components v and u are assumed to be independent of each other, where v is the two-sided, normally distributed random error ($v \sim N(0, \sigma_v^2)$), and u is the one-sided efficiency component with a half-normal distribution ($u \sim |N(0, \sigma_u^2)|$). The maximum likelihood estimation of equation (7) provides estimators for β , λ , and σ^2 , where β was defined earlier, $\lambda = \sigma_u/\sigma_v$, and $\sigma^2 = \sigma_u^2 + \sigma_v^2$. Given the assumptions on the distribution of v and u , Jondrow et al. show that the conditional mean of u given ϵ is equal to

$$(9) \quad E(u | \epsilon) = \sigma_* \left(\frac{f^*(\lambda\epsilon/\sigma)}{1 - F^*(\lambda\epsilon/\sigma)} - \frac{\lambda\epsilon}{\sigma} \right),$$

where f^* and F^* are, respectively, the standard normal density and distribution functions, evaluated at $\lambda\epsilon/\sigma$, and $\sigma_*^2 = \sigma_u^2 \sigma_v^2 / \sigma^2$.

Thus, equations (7) and (9) provide estimates for u and v after replacing ϵ , σ_* , and λ by their estimates. Subtracting v from both sides of (7) results in

$$(10) \quad Q^* = f(X_a) - u = Q - v,$$

where Q^* is the firm's observed output adjusted

for the statistical noise captured by v . Equation (10) is used to compute the vector X_i and to algebraically derive the cost frontier which, in turn, is the basis for obtaining the minimum cost factor demand equations. The latter are then used to calculate the vector X_e .

Data and Empirical Model

Cross-sectional data for a sample of 511 New England dairy farms (excluding the state of Rhode Island) are used to estimate a Cobb-Douglas stochastic production frontier which is the basis for deriving a stochastic cost frontier and related efficiency measures. Following Zellner, Kmenta, and Drèze, we adopt the standard practice of justifying a single-equation model by assuming that farmers maximize expected profits (e.g., Caves and Barton, Kopp and Smith).

The data used in this study are from Dairy Herd Improvement (DHI) production records for the calendar year 1984 combined with data obtained from a mail survey. Descriptive statistics for the variables used in the analysis are given in table 1. The specific model estimated is the following:

$$(11) \quad \ln Q = \ln \beta_0 + \beta_1 \ln X_1 + \beta_2 \ln X_2 + \beta_3 \ln X_3 + \beta_4 D_1 + \beta_5 D_2 + \beta_6 D_3 + \epsilon,$$

where Q is annual milk production per farm measured in hundredweight adjusted to a 3.5% butterfat basis; X_1 is annual consumption of purchased dairy concentrate in tons per farm; X_2 is annual consumption of forage feed in tons per farm which is equal to the consumption of succulent roughage plus dry roughage, assuming a dry matter content of 30% and 90%, respectively; and X_3 is annual variable labor used per farm measured in full time worker-equivalents. The original data set contains information on total labor used per farm; thus, to obtain variable labor one operator per farm is assumed to be fixed, and this is subtracted from total labor. This is not an entirely adequate adjustment since family labor is often considered to be a fixed input (e.g., Stefanou and Saxena). However, data limitations preclude the construction of a more refined measure of labor. D_1 is a binary variable equal to one if the farm has a stanchion barn and a bucket and carry milking system and zero otherwise; D_2 is a binary variable equal to one if the farm is located in Maine or Massachusetts and zero otherwise; D_3 is a binary variable equal to one if the farm is located in Vermont and zero

otherwise; β_i are parameters to be estimated ($i = 0, \dots, 6$); and ϵ is a composed error term defined earlier. The dummy variables capture any effects of milking technology (D_1) and farm location (D_2 and D_3) on the placement of the production frontier.⁴ The variable inputs included in the specification of equation (11) are similar to those recently used by Stefanou and Saxena in their model of Pennsylvania dairy farms.

Results and Analysis

Table 1 presents the maximum likelihood estimates of the stochastic production frontier. For comparison purposes OLS estimates are also shown. All parameter estimates are statistically significant at the 1% level in both models. The only exception is the parameter for D_1 in the production frontier equation which is significant

at the 5% level. Slope parameters across equations are similar, which suggests that the frontier function represents a neutral upward shift of the OLS model. The quasi-function coefficient in both the frontier and the OLS model is about 0.92, and the hypothesis of constant returns to size, based on a restricted least squares regression, is rejected at the 1% level.

The dual cost frontier, derived analytically from the production frontier shown in table 1, is equal to

$$(12) \quad \ln C = 0.014 + 0.091D_1 + 0.660D_2 - 0.069D_3 + 0.611\ln P_{1i} + 0.374\ln P_{2i} + 0.016\ln P_{3i} + 1.091\ln Q^*$$

where C is variable cost of milk production per farm in 1984; D_j is a dummy variable ($j = 1, 2, 3$) as defined above; P_{1i} is price per ton of 16% protein dairy feed in the i th state ($i = 1, 2, \dots, 5$); P_{2i} is price per ton of forage feed in the i th state; P_{3i} is annual wages per worker employed in agriculture, forestry, and fishing in the i th state; and Q^* is annual milk production per

⁴ Connecticut and New Hampshire are combined because preliminary estimations showed that the location effect was almost identical for these two states. Maine and Massachusetts are also combined for the same reason.

^a The top figure is the number of farms, and the figure in parenthesis is the percent of farms.

farm adjusted for any statistical noise as specified in equation (10) above. Input price data for individual farms are not available, which forces us to employ state-level average input prices for 1984.⁵ In general, this is a reasonable assumption considering the relatively small geographical area where the farms in the sample are located and the competitive nature of the markets in question.

The average economic (*EE*), technical (*TE*) and allocative efficiency (*AE*) indexes computed for the sample, shown in table 2, are 70.2, 83.0, and 84.6, respectively. This average technical efficiency measure of 83.0% is very close to the 82.0% reported by Bravo-Ureta based on a probabilistic production frontier model for a sample of New England dairy farms participating in ELFAC (Electronic Farm Accounts). However, the measure is considerably higher than the 69.0% reported by Tauer and Belbase, who

used a corrected ordinary least squares procedure to estimate a production frontier for a sample of New York dairy farms. Similar comparisons for economic and allocative efficiency cannot be made because, as far as we know, no such measures for dairy farms have been reported in the literature.

Table 3 presents a summary of observed, economic, and technically efficient costs along with potential savings for three groups each containing 10% (51 farms) of the farms with the lowest, middle, and highest level of economic efficiency. Based on analysis of variance (ANOVA) and the Kruskal-Wallis (K-W) test, the results indicate that these costs are significantly different across the three groups at the 1% level. The data suggest that the most economically inefficient group in the sample could save an average of \$1.44 per hundredweight if it became technically efficient and \$3.60 per hundredweight if it became economically efficient. In contrast, the figures for the group with the highest economic efficiency are \$0.87 and \$0.96, respectively.

The ANOVA and K-W tests are also used to evaluate the relationship between efficiency and four socioeconomic characteristics of the farms in the sample. The four characteristics analyzed are (a) farm size, measured by the average number of dairy cows in 1984; (b) education, measured by the number of years of schooling completed by the farm operator; (c) extension, measured by the number of extension meetings attended plus farm visits by extension agents during 1982 and 1983; and (d) experience, measured by the age of the farm operator. The results of the K-W and ANOVA tests, shown in table 4, reveal a statistically significant positive relationship between *TE* and farm size, while the opposite is true for *AE* and *EE*. This same pattern is observed for extension. By comparison, experience shows no significant association with *TE* but is inversely related to *EE* and *AE*. Finally, education appears to have no statistically significant association with efficiency in this sample. Even in the cases where a statistically significant difference is observed, the actual efficiency levels across the three farm groups are remarkably close to each other.

Our results concerning farm size and *TE* are consistent with the estimates reported by Grisley and Mascarenhas for Pennsylvania dairy farmers, by Tauer and Belbase for New York dairy farms, and by Bagi for mixed crop and livestock farms in Tennessee. In contrast, no connection between *TE* and farm size was reported by Bravo-Ureta for New England dairy farms, by Byrnes

⁵ The input prices used are (U.S. Bureau of the Census, U.S. Department of Agriculture):

Connecticut: $P_1 = \$172$; $P_2 = \$96.4$; $P_3 = \$11,842$.
 Maine: $P_1 = \$178$; $P_2 = \$79.7$; $P_3 = \$10,735$.
 Massachusetts: $P_1 = \$176$; $P_2 = \$94.6$; $P_3 = \$14,327$.
 New Hampshire: $P_1 = \$192$; $P_2 = \$96.1$; $P_3 = \$11,908$.
 Vermont: $P_1 = \$187$; $P_2 = \$83.3$; $P_3 = \$11,167$.

Table 3. Summary of Observed and Efficient Costs and of Potential Savings

^b Three asterisks indicate significance at the 1% level.

et al. for Illinois grain farms, and by Bagi for crop farms in Tennessee. The lack of relationship observed in our sample between education and *TE*, and between experience and *TE*, although surprising, is in agreement with the findings of Tauer and Belbase for New York dairy farms. Our results regarding the relationships between the socioeconomic variables and *AE* and *EE* as well as between extension and efficiency cannot be compared to other U.S. samples because no comparable studies have been published. However, studies using data from developing countries have also yielded conflicting results concerning the relationship between *TE* and socioeconomic variables similar to those in-

cluded in this paper (e.g., Belbase and Grabowski, Huang and Bagi, Kalirajan).

Concluding Comments

This paper extends Kopp and Diewert's efficiency decomposition methodology from a deterministic to a stochastic framework and uses the latter to analyze efficiency in dairy production. The methodology developed here yields efficiency measures that are not distorted by statistical noise. In addition, the methodology makes it possible to calculate not only technical but also allocative and economic efficiency relying solely

^a The groups for each of the four socioeconomic characteristics are defined as follows:

Farm Size -	Group 1: <44 cows;	Group 2: 44-64 cows;	Group 3: >64 cows;
Education -	Group 1: <12 years of schooling;	Group 2: 12 years of schooling;	Group 3: >12 years of schooling;
Extension -	Group 1: no extension contacts;	Group 2: 1-7 extension contacts;	Group 3: >7 extension contacts;
Experience -	Group 1: <37 years of age;	Group 2: 37-52 years of age;	Group 3: >52 years of age.

^b The efficiency index is the average for each group.

^c Three asterisks indicate significance at 1% level; two, at the 5% level.

on the econometric estimation of a production frontier.

The analysis shows that, for our sample of New England dairy farms, average technical efficiency is 83.0%, average economic efficiency is 70.2%, and average allocative efficiency is 84.6%. These results suggest little difference, on average, between technical and allocative inefficiency, which is of interest given the controversy regarding the relative importance of the various components of efficiency (Leibenstein, 1966, 1978; Comanor and Leibenstein; Stigler). However, the analysis shows that focusing only on technical efficiency understates the benefits that could be derived by individual farmers as well as society from an improvement in overall performance. Analyses of the relationship between efficiency and four socioeconomic variables—farm size, education, extension, and experience—reveal that, despite some statistically significant associations, efficiency levels are not markedly affected by these variables. Further experimentation with different data sets and alternative methodologies is needed before the sensitivity of the results to the research design can be thoroughly judged.

Prospect Theory and Risk Preferences of Oregon Seed Producers

Alan Collins, Wesley N. Musser, and Robert Mason

Prospect theory relates risk preference classifications to gains and losses from a reference income level. This study applies prospect theory to reinterpret historical studies of risk preferences of Oregon grass seed growers. A significant relationship between changes in classifications of preferences and changes in income was found. Results indicated that those who lost income were concentrated in the category of changing to risk preferrers. Income changes calculated from crop combinations were also found to be correlated in a theoretically correct pattern with positive measures of risk from crop enterprises. The research therefore is consistent with further applications of prospect theory to farm management.

Key words: expected utility theory, prospect theory, risk preferences, variance estimation.

Substantially different risk preferences have been reported among a single population of Oregon grass seed producers at different points in time (Halter and Mason, Whittaker and Winter). Similar intertemporal instability of risk preferences among agricultural producers has been reported in India (Binswanger). From the results in Oregon, Fleisher and Robison concluded that the elicitation methods were fundamentally flawed, or risk preferences do change over time.

In the Oregon research, the possibility of errors was minimized by survey research center data collection and polynomial curve fitting of utility functions. These methods minimize interview errors (Musser and Musser, Fleischer and Robison) and functional form specification errors (Buccola and French, Dillon and Scandizzo, Musser et al.), respectively. However,

measurement errors in variables could bias utility function coefficients (Knowles). In addition, response measurement errors may result if the elicitation process is beyond human cognitive capacity. In this case, changes in measured risk preferences could be the result of random errors in responses (Musser and Musser).

While methods problems cannot be dismissed, the alternative explanations of systematic changes in risk preferences do merit attention. Earlier research on these data indicated that changes in wealth could not explain the preference shifts within the expected utility framework. Another possibility is prospect theory, which predicts individuals can alternate between risk-averse and risk-seeking behavior (Kahneman and Tversky). This theory has been applied in natural resource economics to reconcile differences between willingness to pay and willingness to sell (Gregory; Cummings, Brookshire, and Schulze).

This paper investigates the use of prospect theory to rationalize changing risk preference results from the earlier Oregon studies (Halter and Mason, Whittaker and Winter). The next section of the paper summarizes relevant features of prospect theory and its implications for these earlier studies. The subsequent two sections present further empirical analysis of the risk preference data from these studies. Changes in risk preferences are related to changes in gross

The late A. N. Halter participated in collecting the sample data and estimated utility functions. Brian Freeze, Jim Cornelius, and Steve Buccola made helpful suggestions on the research in this paper, and William McSweeney and two anonymous referees made helpful comments on earlier drafts of this paper.

farm income as a measure of wealth changes between sample periods. In addition, managerial responses in enterprise organization are compared to gross income changes to link wealth changes with managerial behavior.

Aspects of Prospect Theory

While prospect theory has roots in expected utility theory, it is strongly influenced by cognitive theories of bounded rationality (Simon). Kahneman and Tversky developed the theory to rationalize divergences in behavior from predictions of expected utility theory. Their earlier work on decision heuristics (Tversky and Kahneman) strongly influenced this theory. Prospect theory describes decisions as having two stages—editing and evaluation. Editing simplifies the decision problem for the evaluation stage. For example, alternative outcomes of a decision are redefined as gains and losses from a reference point (P_r), which is usually the current wealth or equity capital position of an individual.

Evaluation utilizes an adaption of the expected utility decision rule:

$$(1) \quad V(D_j) = \sum_{i=1}^n \pi(p_i) v(x_i),$$

where D_j is a decision alternative, x_i is a gain or loss outcome with a probability p_i , n is the number of edited outcomes, $\pi(p_i)$ is a weighting function based on p_i , and $v(x_i)$ is a value function. The weighting function is related to subjective probabilities but does not exactly follow probability rules. Specifically, $\pi(p_i) > p_i$ for small p_i and $\sum_{i=1}^n \pi(p_i) < 1$. In evaluation, the alternative from the edited prospects that maximizes $V(D_j)$ is chosen.¹

The value function has a similar role to a utility function but is defined on gains and losses in wealth rather than level of wealth. As illustrated in figure 1, specific properties are pos-

tulated for $v(x_i)$. For $x_i > 0$, the individual is risk averse, $v''(x) < 0$, and, for $x_i < 0$, an individual is a risk seeker, $v''(x_i) > 0$. A discontinuity in $v(x)$ is assumed at $x_i = 0$ with $v'(x_i) < v'(-x_i)$ for $x_i > 0$. Kahneman and Tversky proposed the properties of $v(x_i)$ based on experimental evidence of individual probabilistic decisions. Schurr recently confirmed this shape in experiments on risky business negotiations on commodities.

To predict changes in risk preferences and behavior over time with prospect theory, the concept P_r is used. Prediction is possible in situations where decisions are based on a P_r which differs from the status quo in individual wealth. These situations can occur when decision makers have not yet adapted to recent changes in wealth or when expectations of future wealth positions have been incorporated into P_r . In such cases, gains and losses from a decision are evaluated in connection with recent wealth changes or relative to an expected level of wealth.² The effect of a failure to incorporate losses into P_r is illustrated in figure 1. Assume a recent wealth loss (Y_L), which is not incorporated into P_r , so that $v(x_i)$ is stable. Then, prospects are evaluated as $v(Y_L + x_i)$. Now, even gains are evaluated with a convex value function as long as Y_L

² Admittedly this failure to adapt P_r is ad hoc. However, such ad hoc dynamics are also used in economics research. For example, Deaton and Muehlbauer provide a review of such inflexibility in consumption; Langemeier and Patrick is a recent application of such models to consumption behavior of farm families.

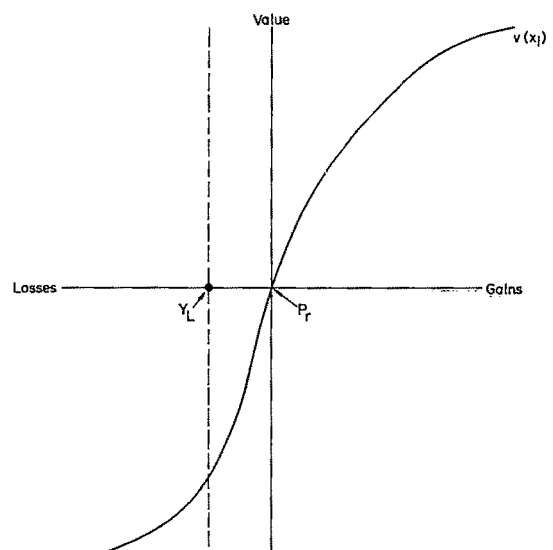

Figure 1. Value function hypothesized from prospect theory

¹ Prospect theory, like most psychological theories, is a positive rather than normative theory. Unlike decision theory, all the theoretical constructs need not be empirically estimated. The focus is on their behavioral implications rather than postulates. Positive economics is similar in that respect; consumer utility functions and firm production functions need not be estimated to test theoretical hypotheses. For example, Kahneman and Tversky do not expect $v(x_i)$ and $\pi(p_i)$ to be estimated. Nevertheless, some empirical findings in farm management support their assumptions. Kahneman and Tversky cited research on utility functions from agricultural managers as being consistent with $v(x_i)$ as do Anderson, Dillon, and Hardaker. Bessler and SriRamaratnam et al. report subjective probability distributions that have some properties similar to $\pi(p_i)$.

+ $x_i < 0$. Thus, individuals in a loss situation would exhibit risk-seeking behavior. This failure to adapt to recent wealth changes for individuals in a loss situation can be related to commonly perceived behavior. Kahneman and Tversky cite a well-known tendency toward betting on "long shots" near the end of a betting day as an example of failure to adapt P_r . A failure to adapt to gains is harder to relate to common behavior (Kahneman and Tversky, pp. 286–88). Logically, this failure would have the opposite effect of increasing risk aversion. Isen, Nygren, and Ashby recently found increasing risk aversion in individuals that received a prior gain. However, they explained their results as a shift in $\pi(p_i)$ rather than P_r .

In this study, Pratt's absolute risk aversion coefficient (R) for individual producers is used to measure responses of P_r to gains and losses in wealth. Prospect theory provides no prediction of the changes in R if changes in wealth are incorporated in P_r . However, assuming failure to incorporate prior wealth changes in P_r gives definite predictions for changes in R . Recent losses (gains) in wealth result in $v(x_i)$ being convex (concave) for both gains and losses. Thus, measures of R would tend to be negative (positive) after the wealth change. Whatever the measure of R before the wealth changes, intertemporal changes in R therefore should tend to have the same sign as recent changes in wealth. This implication of prospect theory is evaluated for the Oregon grass seed producers in this research.

Methods

Data for this study are from three surveys of Oregon grass seed producers in March 1973, April 1974, and December 1975. Data on crop acreages and other farm characteristics were collected for the 1973, 1974, and 1975 crop years. Risk preferences were elicited in the last two surveys based on gross farm income from completed 1973 and 1974 crop years, respectively. Thus, cropping decisions in the last two surveys lagged realized income on which risk preferences were based. Of the forty-four producers interviewed in 1974, thirty-seven completed the 1975 survey.

Risk Preferences

Risk preferences were elicited with the Ramsey method (Halter and Mason). Gross farm income

was used for accuracy in recall during the interviews. Net income (or wealth) would have been more desirable theoretically. However, gross income does correspond with the standard assumption of the stochastic component of net income in production (Dillon). Individual utility functions were fit to linear, quadratic, or cubic functional forms based on goodness of fit criteria and visual inspection of scatter plots (Halter and Mason). These criteria allowed functional form to vary from 1974 to 1975. Absolute risk aversion coefficients (R) were calculated from the estimated functions at sample-reported 1973 and 1974 gross farm income levels.

Change in gross farm income between 1973 and 1974 ($\Delta_I = 1974 \text{ income} - 1973 \text{ income}$) was used to measure wealth changes. More accurate measures of wealth changes would include data on changes in net farm income, equity capital, household consumption spending, and nonfarm income. These data are harder to collect accurately and were not included in the surveys of Oregon grass seed producers. With this wealth change measure between 1973 and 1974, the absolute risk aversion coefficient prior to the wealth change was compared to that after the change ($\Delta_R = R_{1974} - R_{1973}$). A chi-square classification table was used to test for independence between Δ_I and Δ_R as measures of wealth and risk preference changes, respectively.

Behavioral Risk Responses

Given the behavioral focus of prospect theory, this study also considers the managerial response in crop enterprise organization among the Oregon grass seed producers to the changes in risk preferences. While measurement of risk levels of decisions is a difficult theoretical and empirical issue (Hey, Young), this study assumed variance of gross income (VAR_I) approximated risk in behavior (Levy and Markowitz, Robison and Barry). While subjective probabilities would have been more consistent with decision theory and reflected differences in land, management, and other resources among the farmers, they were unavailable for this study. Thus, historical risk measures were used to proxy individual subjective distributions.

Crops included in this analysis were annual rye, perennial rye, tall fescue, bentgrass, Merion bluegrass, wheat, oats, and barley. Some producers had livestock and/or other crops; however, inadequate sample data were available to include these enterprises in variance of gross

income. A time series of annual acreage, price, and yield data for each of the crops were collected for 1954 to 1974 (Oregon State University Extension Service). County averages for Linn County, where the majority of the sample producers were located, were used for the analysis. Gross incomes were inflated to 1974 price levels with the "Index of Prices Paid by Farmers for Production Items" (U.S. Department of Agriculture).

Using criteria of Peck and Young for positive objective risk measures, risk measures ($V(X, Y)$) were calculated as weighted moving averages of historical forecast errors of gross income:

$$(2) \quad V(X, Y) = \sum_{t=1}^n w_t (X_t - E_t(X)) (Y_t - E_t(Y)),$$

where $E_t(X)$ and $E_t(Y)$ are forecasted expected values of X and Y in time period t , and w_t are weights on forecast errors from previous periods where $\sum_{t=1}^n w_t = 1$. $V(X, Y)$ is a mean-squared error estimate of variance of a variable when $X = Y$ and of covariance between X and Y when $X \neq Y$.

This research utilized an adaptive expectation approach to jointly specify forecasted expected values and weights. Following Nerlove, expected values, $E_t(Z)$ were calculated with estimated coefficients of expectations (b_z) from supply response models:

$$(3) \quad E_t(Z) = b_z Z_{t-1} + (1 - b_z) Z_{t-2} + (1 - b_z)^2 Z_{t-3} + \dots$$

Because supply response models including risk variables (Just) were unavailable, separate weights could not be used on expected values and risk indices. Thus, b_z coefficients were also used as estimates of w_t . Published estimates of b_z were adapted for this research. The average of estimates for coefficients of expectation (0.21) for similar crops in the Willamette Valley (Ryan, Conklin, and Edwards) were used for grass seed crops. Similar models were unavailable for grains in Oregon or the Pacific Northwest. Therefore, a value of 0.77 from a national model for this period (Lidman and Bawden) was used for grains because similar models were unavailable for Oregon or the Pacific Northwest. Minor adjustments were made in the geometric patterns of weights to account for data availability and to insure that they summed to one (table 1). A simple average of the two weights was used to es-

timate covariances between grass seeds and grains.³

Separate variance-covariance matrices for crop gross incomes were calculated for 1974 and 1975. These estimated risk matrices were appropriate for the 1974 and 1975 planting expectations, respectively. Estimates of VAR_t for both crop portfolios were then formed with individual producer crop acreages and the estimated risk matrices.

These variances of gross farm income were used to test the behavioral implications of prospect theory arising from wealth changes. Forecasted gross income variance for 1974 crop selection was the behavioral measure prior to the wealth change; this same variance for 1975 crop selection was used for subsequent behavior measurement. Changes in variance ($\Delta_v = VAR_{1975} - VAR_{1974}$) were negative for twenty-eight of the thirty-seven observations. The large increase in realized grain prices in 1973 resulted in a large forecast error which was weighted by 0.75 in 1974. Grain prices stabilized in 1974 so the most recent forecast error was much smaller for 1975, and VAR_{1975} was smaller than VAR_{1974} for many producers. With such a large proportion nega-

³ A potential weakness of this method of forming $E_t(Z)$ and w_t is the fundamental identification problem between adaptive expectations and partial adjustment models. Nerlove recognized this problem, and Doran recently provided some statistical methods to test for these alternative explanations in an estimation context. Obviously, the differential length of weights in table 1 could be consistent with partial adjustment behavior of annual versus perennial crops. With that interpretation, these weights are inappropriate for estimating statistical moments. On the other hand, it is plausible that a longer time period would be used in forming expectations on perennials simply because of their longer future production potential. Therefore, these estimates were assumed to reflect adaptive expectations so that an empirical source of w_t was available.

tive, a chi-square test with Δ_v would not be meaningful. Therefore, risk in cropping responses was evaluated with Spearman's rank correlation coefficients (ρ_s) between Δ_v and other variables. Student's t -tests were used to test $H_0: \rho_s = 0$ against $H_1: \rho_s > 0$ (Siegal).

Correlation analyses were also used to relate estimated gross income to Δ_v . A large number of the sample reported the same gross increase in 1973 and 1974 so that Δ_i had a concentration of zeroes. Estimated gross incomes realized in 1973 and 1974 were therefore substituted for sample estimates. Changes in estimated gross income ($\Delta_G = 1974$ gross income–1973 gross income) and percentage change in estimated gross income between 1973 and 1974 ($\%\Delta_G$) were calculated with realized county average gross income per acre and sample crop acreages. Because prior losses in wealth are hypothesized to lead to increasing risky behavior, a negative relationship is expected between Δ_v and Δ_G or $\%\Delta_G$. In the correlation analysis, $-\Delta_G$ and $-\%\Delta_G$ were used so that hypothesized coefficients would be positive.

Results

Tabulations of risk preference classifications for the 1974 and 1975 surveys are reported in table 2. These data demonstrate the instability between the two samples reported in Whittaker and Winter. The only stability was in total numbers in the risk-preferring category—eleven in 1974 and twelve in 1975. Especially surprising is the small number of producers with the same classification in both years, only nine out of thirty-seven. Not surprisingly, $X^2_{(4)} = 4.09$ so that the hypothesis that the samples are independent cannot be rejected.

The relationship of Δ_R to Δ_i is presented in table 3. More than 40% of the sample reported the same gross income. Both the same and more

income categories had equal numbers moving toward risk-seeking and risk-avoiding preferences. The ambiguity in the more income category is related to an unknown pattern of adapting their reference point to increases of wealth. Isen, Nygren, and Ashley also had ambiguous results for income gains. Individuals with less gross farm income and consequently smaller wealth likely would not have adapted their P_i and, thus, evaluate gains as $V(Y_L + x_i)$ in figure 1. While the numbers are small, five out of six changed to a more risk-seeking classification. This finding is consistent with the implications of prospect theory. The chi-square test of independence supported this interpretation: $X^2_{(4)} = 9.89$ so that the null hypothesis of no association can be rejected at the 5% level of significance. Correlation analysis of Δ_G with Δ_R and Δ_v is reported in table 4. The sample correlation coefficient between $-\Delta_G$ and Δ_v equaled 0.30. With $t_{(35)} = 1.88$, $\hat{\rho}_s$ supports H_1 of $\rho_s > 0$ at

the 5% level of significance. In addition, Δ_V and $-\% \Delta_G$ had a $\hat{\rho}_s$ of 0.33, with a $t_{(35)} = 2.072$. With this statistic, H_0 can be rejected at the 2.5% level. These tests showed that estimated gross income declines were correlated with increases in risk-seeking behavior.

The $\hat{\rho}_s$ value between $-\Delta_G$ and $-\Delta_R$ was only 0.12 and between $-\% \Delta_G$ and $-\Delta_R$ was 0.26. The signs of these statistics are consistent with the chi-square analysis which showed reduction in gross income leading to risk-seeking preferences. The latter was significant at the 10% level, which confirms the potential empirical relevance of $\% \Delta_G$ rather than Δ_G . Perhaps, small relative changes in wealth, which could have a large absolute value for large farms, are simplified to zero in the editing stage. The $\hat{\rho}_s$ between $-\Delta_R$ and Δ_V is quite small and insignificant. Δ_R likely had more measurement error than Δ_G .

The significant relationships between $-\Delta_G$ and Δ_V , and $-\% \Delta_G$ and Δ_V support the prediction of prospect theory used in this study that declines in wealth can result in increasingly risky behavior. This relationship does not necessarily imply that the sample tended to become risk seekers with declines in wealth but only that absolute risk aversion coefficients decreased as wealth decreased.

Conclusions

This paper reinterpreted the historical studies of risk preferences of grass seed producers in the Willamette Valley of Oregon from the perspective of prospect theory. Prospect theory was used to explain intertemporal instability of risk preferences through an assumption of a failure to incorporate prior changes in wealth into a decision maker's reference point for evaluation for outcome gains and losses. By using this assumption within the framework of prospect theory, changes in Pratt absolute risk aversion coefficients were significantly related to reported prior gross income changes in a manner consistent with prospect theory. In addition, a significant relationship was found between risk behavior as predicted by prospect theory and wealth changes measured with changes in gross income estimated from reported crop acreages.

This analysis is subject to numerous empirical limitations. Besides the well-known measurement errors in methods to estimate risk preferences and objective probability distributions, assumptions were included on measuring risk with

variances, using gross farm income as a wealth change measure, and only using the field crops to calculate gross farm income. Given these problems, the evidence supporting prospect theory is especially noteworthy. However, the results are not supportive of elicitation of risk preferences. Absolute risk aversion coefficients from elicited data did not predict risky behavior as well as changes in income.

This historical evidence supports further study of the application of prospect theory in farm management and finance. For example, the theory is an alternative to other explanations of behavior related to the recent farm financial stress problems such as Robison, Barry, and Burghardt and Featherstone et al. Prospect theory would predict that farmers in a loss situation would assume riskier managerial position. If financial risk increases due to accumulated unpaid debt, business risk would not be reduced, and may be increased. This pattern would suggest that farmers as a whole would have risk-preferring preferences consistent with a worsening loss situation. Future applications of prospect theory would require additional refinement of the relationships between prospect theory and the measures used in this paper. More important, such work should emphasize (a) direct behavioral linkages with changes in income and (b) the research and extension implications of this theoretical relationship.

Robustness of the Mean-Variance Model with Truncated Probability Distributions

Steven D. Hanson and George W. Ladd

The known sufficient conditions for the mean-variance framework to produce expected utility results are violated in the presence of truncated probability distributions. A theoretical simulation is conducted to examine the ability of the linear mean-variance model to approximate expected utility results when the income distribution is truncated by the use of commodity option contracts. The mean-variance model is shown to produce solutions that are close approximations to the expected utility model results under the assumptions of constant absolute risk aversion and normally distributed prices. However, some inconsistency was found between the comparative static results of the two models.

Key words: futures, mean-variance, options, risk management.

The mean-variance (MV) framework has been a popular method for ordering choices into efficient and inefficient sets since its development by Markowitz. The problem of portfolio selection is reduced to choosing from a set of alternatives that provide minimum variance for given levels of expected return (i.e., the MV efficient set). The MV framework has been used to study a wide range of economic decisions made under risk such as the allocation of fixed assets in the presence of uncertain production processes (Freund), the demand for money (Tobin), and corporate financial decisions (Rubenstein). For a review of applications of mean-variance analysis in agricultural economics, see Robison and Brake; and Musser, Mapp, and Barry. Much of the previous research on risk management with futures contracts has employed the MV framework (e.g., see Anderson and Danthine, Kahl). Recently, commodity options contracts have become available as a risk management tool. Wolf has incorporated options contracts into an MV framework.

The inclusion of options in a decision maker's (DM's) portfolio results in truncated probability distributions that violate the standard assumptions used to justify the use of an MV representation of expected utility. Indeed, a variety of risky decision problems can be characterized by truncated probability distributions: bankruptcy, starvation, insurance schemes, limited liability, and price support and deficiency payment programs. This study examines the approximating ability of the standard linear MV model when the income probability distribution is truncated by the use of commodity options; it examines the robustness of the linear MV model to a violation of MV assumptions.

The Mean-Variance Model

The MV framework focuses on the first two moments of the underlying probability distribution. Its popularity can be traced to the tractable theoretical results it produces and to its computational convenience. Unfortunately, its straightforward nature results from some restrictive assumptions that are violated when options are included in a portfolio.

Specifying an expected utility function in terms of the first two moments of the underlying attribute's distribution has been shown to be consistent with the expected utility hypothesis only if at least one of the following sufficient con-

Journal Paper No. J-13596 of the Iowa Agriculture and Home Economics Experiment Station, Project No. 2858. Partial funding support was provided by the Michigan State University Experiment Station.

The authors are grateful to anonymous referees for their valuable suggestions.

ditions is met: (a) the DM's utility function is quadratic (Tobin), (b) the DM has a concave utility function, and the random attribute is normally distributed (Samuelson), (c) the random attribute is a monotonic linear function of a single random variable (Meyer); sometimes referred to as the location-scale condition. Because these are only sufficient conditions, the MV framework may be consistent with the expected utility (EU) hypothesis under other conditions.

These sufficient conditions are often argued to be either violated or unacceptable. Baron shows that quadratic utility is a necessary and sufficient condition for MV representation of expected utility to be valid when the random variables are not restricted. Unfortunately, quadratic utility usually is viewed as an unacceptable preference function because it implies increasing absolute risk aversion and produces negative marginal utility as income rises above some given level.

Some have justified the use of the MV framework by assuming that condition (b) is satisfied (e.g., Anderson and Danthine). Others have criticized this assumption because few random variables take on values from negative to positive infinity and are symmetrically distributed, as is implied by the normality assumption.

Many utility functions are concave functions of income and can be used with a normally distributed income variable to yield an MV representation of the expected utility function. Only the negative exponential utility function, $U(y) = \alpha - \exp(-Ay)$, where $\alpha > 0$, in conjunction with a normally distributed attribute, y , will result in an expected utility function identical to the "standard" linear MV model, which is typically specified as¹

$$(1) \quad \text{Max}_x \hat{U} = \mu_y - (A/2) \sigma_y^2,$$

where μ_y is expected value of end-of-period income, A is the Arrow-Pratt measure of absolute risk aversion, σ_y^2 is variance of end-of-period income, and x is a vector of choice variables. The negative exponential utility function implies that the DM exhibits constant absolute risk aversion (CARA) and increasing relative risk aversion. The literature on risk preference characteristics

is somewhat inconclusive, although there is some evidence that decision makers exhibit decreasing absolute risk aversion (King and Robison). Regardless, most studies have been willing to accept the assumption of CARA to obtain the desirable properties of the standard MV model, although not all studies employing MV have used the negative exponential function.

Meyer and Robison have used condition (c) to justify the MV framework. Meyer has shown that the MV and EU frameworks are consistent regardless of the distribution of the random variable whenever a random outcome variable is a monotonic linear function of a single underlying random variable. Current work by Nelson is attempting to generalize Meyer's results to a class of models containing multivariate risks which are elliptically symmetric.

Some risky decision-making environments violate the known sufficient conditions for consistency. Newbery and Stiglitz recognize that risk is not symmetric for some decisions such as insurance schemes, and MV analysis may be seriously misleading for those decisions. One implication is that the MV framework may produce significant errors when the income distribution is truncated in the tails.

Much of the debate involving MV and EU models has focused on the approximating ability of the MV model. Levy and Markowitz show that the MV model provides reasonable approximations to EU maximization when the opportunity set contains a low probability of extreme outcomes. Tsiang shows that an MV framework approximates the EU maximization model when certain restrictions are placed on the skewness of the income distribution. Meyer and Rache show that, with "few enough" observations, there is no statistically significant difference between MV and EU rankings because the random alternatives are estimated imprecisely. Porter shows that MV sets of randomly constructed stock portfolios are consistent with EU models, except for portfolios having small means and variances. Tew and Reid explore the performance of the MV framework using firm specific, non-tradable investments for a representative farm in Georgia. Their results indicate the MV framework performs well in selecting investments that maximize expected utility. Robison and Barry argue for the use of the MV model on the basis of its ability to produce useful analytical results when more general models become too complex. Thus, there is some support, both empirical and deductive, for use of the MV framework even when its sufficient conditions are

¹ Robison and Barry formulate a linear MV model by claiming that A is the slope of a linear tangent at equilibrium to the isoutility line and its MV-efficient set. The assumptions of constant, increasing, and decreasing absolute risk aversion are then introduced through slope changes.

violated. In what follows, we show that conditions (b) and (c) are violated when the income distribution is truncated by including options in a portfolio. Then we examine the robustness of the linear MV model in the presence of truncated probability distributions for a DM with constant absolute risk aversion.

Income Probability Distribution with Commodity Options

To derive the distribution of income when options are available, assume that the DM has the amount Q of a single asset that may be sold at a specified future date in the cash market for some unknown spot price, P , or in the futures market for a certain price, P_f , or the DM may purchase the option to sell the output for a certain price, P_e . The output Q may be divided among the three markets in any way. The DM may sell a total amount in the cash, futures, and options markets that is greater than Q , may go long in the futures market, or write put options instead of selling them. There are assumed to be no transaction costs, basis uncertainty, or margin calls.

The only uncertainty faced by the DM is the output price P , and the DM can reduce uncertainty by marketing output in the futures or the options market. The DM's choice variables are the amounts marketed in the futures and options markets. The model is single period in nature and assumes that the initial positions are maintained until the end of the period at which time all cash, futures, and options transactions will take place. The quantity of output to be sold, the futures contract selling price, the exercise price, and the put option premium are known, exogenous variables to the DM. The DM's end-of-period income can be represented as equation (2):²

$$(2) \quad y(P) = PQ + x(P_f - P) + Iz(P_e - P) - zk,$$

where $y(P)$ is total end-of-period income, P is random end-of-period spot price, P_f is localized futures price for end-of-period delivery, Q is certain end-of-period output level, I is an indicator variable ($= 1$ if $P < P_e$, or $= 0$ if $P \geq$

P_e), P_e is localized exercise price of a put option, k is put option premium per bushel, x is the number of bushels of futures contracts, z is the number of bushels of put option contracts.

Expression (2) is derived from two distinct income functions:

$$(3) \quad y(P) = PQ + x(P_f - P) + z(P_e - P) - zk \quad \text{if } P < P_e,$$

$$(4) \quad y(P) = PQ + x(P_f - P) - zk \quad \text{if } P \geq P_e$$

by introducing the indicator variable I . It is clear from these expressions that sufficient condition (c) for adequacy of the standard MV framework is violated in the presence of options. For example, if $Q - x > 0$ and $Q - x - z < 0$, then $\partial y / \partial P < 0$ for all $P < P_e$ and $\partial y / \partial P \geq 0$ for all $P \geq P_e$. Income is not a monotonic transformation of price; it may be a negative or a positive transformation, which violates condition (c).³

The DM is assumed to believe that output price is normally distributed with a known mean μ_P and variance σ_P^2 . Because P is normally distributed and $y(P)$ is a linear function of P , if $P < P_e$ the unconditional mean and variance of income are [from (3)]

$$\mu_{y1} = (Q - x - z)\mu_P + xP_f + z(P_e - k),$$

$$\sigma_{y1}^2 = (Q - x - z)^2 \sigma_P^2.$$

If $P \geq P_e$, $y(P)$ is normally distributed with unconditional mean and variance μ_{y2} and σ_{y2}^2 [from (4)],

$$\mu_{y2} = (Q - x)\mu_P + xP_f - zk,$$

$$\sigma_{y2}^2 = (Q - x)^2 \sigma_P^2.$$

Define $y(P_e)$ as the value of $y(P)$ from (3) or from (4) with $P = P_e$. The income density function corresponding to equation (2) can be shown to be⁴

$$(5) \quad w(y) = I_1 \exp [-(y - \mu_{y1})^2 / 2\sigma_{y1}^2] / \sigma_{y1} \sqrt{2\pi} + I_2 \exp [-(y - \mu_{y2})^2 / 2\sigma_{y2}^2] / \sigma_{y2} \sqrt{2\pi},$$

where

$$I_1 = 1 \text{ for } y < y(P_e) \quad \text{if } (Q - x - z) > 0, \\ \text{or for} \\ y \geq y(P_e) \quad \text{if } (Q - x - z) \leq 0, \\ = 0 \text{ otherwise;}$$

² Commodity options currently traded on the organized exchanges are options on commodity futures contracts. The income function in equation (2) treats the options as options on the spot commodity. The assumption of a certain basis level results in equivalence between the two types of options. That is, if the basis is known with certainty, then an option on a futures contract is equivalent to an option on the underlying spot commodity.

³ Sufficient condition (c) is violated when options are included in a portfolio. However, as Meyer points out, it may be difficult to reject the null hypothesis that sufficient condition (c) holds when using empirical data.

⁴ The derivation is presented by Hanson.

$$I_2 = 1 \text{ for } y \geq y(P_e) \quad \text{if } (Q - x) \geq 0, \\ \text{or for} \\ y < y(P_e) \quad \text{if } (Q - x) < 0, \\ = 0 \text{ otherwise.}$$

The first term of (5) corresponds to equation (3); the second, to equation (4). This distribution is the sum of two truncated normal distributions, for which the mean, variance, and bounds of integration depend on μ_p , σ_p^2 , P_f , P_e , k , Q and the DM's choices of x and z . The distribution represented by equation (5) can take on a variety of forms dependent on the DM's positions in the futures and options markets. It is clear from (5) that sufficient condition (b) is violated because the income distribution is not normal when the DM takes a position in the options market. Thus, sufficient conditions (b) and (c) for the standard MV model to produce results that are consistent with expected utility maximization are violated when options contracts are available, and an alternative framework is needed.

Expected Utility Maximization

If the DM is assumed to maximize expected utility and faces the income function and conditions indicated by equation (2), then the DM chooses futures and options positions to satisfy equation (6):

$$(6) \quad \text{MAX}_{x,z} \bar{U} = \int_{-\infty}^{\infty} U(y)w(y)dy,$$

where \bar{U} is the DM's expected utility given the choice of x and z ; $U(y)$ is the DM's utility function, assumed to exhibit CARA; and $w(y)$ is the income distribution specified by equation (5). Solving equation (6) yields the optimal futures and options positions, x^* and z^* . Because equation (6) has no explicit algebraic solutions when the DM uses options, solution techniques involving numerical integration and optimization are required.

Optimal Hedging in a Mean-Variance Framework

Expression (5) shows that the assumptions underlying the linear MV model are violated when options are held by the DM. The linear MV model may, however, produce acceptable quantitative results or useful insights into the impacts

of options on optimal market positions. To investigate this possibility, this section extends the linear MV model to include options.

Three different MV models are used to study the optimal market positions under various situations. Model 1 presents the standard result for a DM who uses only the cash and futures markets and corresponds to the use of a security which does not truncate the income distribution.⁵ Model 2 includes the cash and options market and corresponds to the use of a security which truncates the income distribution. Model 3 includes the cash, futures and options markets and corresponds to the use of a security which truncates the income distribution and a security that does not truncate the income distribution. Model 1 contains no truncation problem but models 2 and 3 do.⁶ Each model is solved using (1), and implications of the solutions are discussed. As will be seen later, despite the violation of the sufficient conditions for MV consistency with EU, the model does provide useful insights into the numerically generated EU results.

These models use the following additional definitions: T is localized value of the option at the end of the period = $\max [0, P_e - P]$; μ_T is expected value of the option; σ_T^2 is variance of the value of the option; $\sigma_{p,T}$ is covariance between the value of the option and the spot price.

Model 1: Cash and Futures with Certain Output (CF)

Model 1 examines the optimal hedge in a futures market for a DM having a fixed end-of-period output level. The end-of-period income function is

$$(7) \quad y = PQ + x(P_f - P).$$

Solving (1) subject to (7) yields (8) as the optimal futures position

$$(8) \quad \hat{x} = Q + \frac{(P_f - \mu_p)}{A\sigma_p^2}.$$

It is useful to discuss the results in each MV model in terms of the hedging and speculative components. The first term in the solution (8) is the hedging component; it is simply the futures position that minimizes the variance of end-of-period income. The second term is the spec-

⁵ These results have been reported in previous work: for example, see Anderson and Danthine.

⁶ Models 2 and 3 are derived in Hanson.

ulative component; it is the futures position that results if the DM does not have any cash position and obtains his entire end-of-period income from the futures market. If the futures market is considered unbiased (i.e., $P_f = \mu_p$), then the speculative component disappears, and the optimal futures position is the traditional hedge where the futures position is equal and opposite the cash position. However, if the DM believes the futures market is biased, then the DM believes that, on average, profits can be made by speculating in the futures market. The futures position is altered by the amount of believed bias adjusted by the level of risk aversion and price variability. Increases in risk aversion lead to smaller speculative positions. If a DM is infinitely risk averse, the speculative component is zero, and the futures position equals the traditional hedge.

Model 2: Cash and Options with Certain Output (CO)

Model 2 examines the options market position. End-of-period income consists of revenue from the cash and options markets less the cost of purchasing options. The income function can be written as

$$(9) \quad y = PQ + zT - zk,$$

where both P and T are random variables. Choosing z to maximize (1) subject to (9) yields

$$(10) \quad \hat{z} = -\frac{Q\sigma_{p,T}}{\sigma_T^2} + \frac{(\mu_T - k)}{A\sigma_T^2}.$$

The first and second terms represent hedging and speculative components analogous to model 1. It can be shown that the absolute value of the ratio $\sigma_{p,T}/\sigma_T^2$ will always be greater than one. This implies that in the absence of any speculative position, the DM will always overhedge in the options market. The result occurs because the overhedge position in the options market minimizes the variance of end-of-period income. The speculative component will modify the optimal market position in a manner analogous to model 1.

Model 3: Cash, Futures, and Options with Certain Output (CFO)

Model 3 considers a DM who is able to use futures and options contracts. Income now in-

cludes revenue from the cash, futures, and options markets, and the cost of purchasing options, and can be expressed as

$$(11) \quad y = PQ + x(P_f - P) + zT - zk.$$

Maximizing (1) subject to (11) yields the optimal market positions in the futures and options markets:

$$(12) \quad \hat{x} = Q - \frac{(P_f - \mu_p)\sigma_T^2 + (\mu_T - k)\sigma_{p,T}}{A(\sigma_{p,T}^2 - \sigma_p^2\sigma_T^2)},$$

$$\hat{z} = -\frac{(P_f - \mu_p)\sigma_{p,T}^2 + (\mu_T - k)\sigma_p^2}{A(\sigma_{p,T}^2 - \sigma_T^2\sigma_p^2)}.$$

The optimal futures market position consists of a hedging and speculative component, and the optimal options market position simply consists of a speculative component. In the absence of any speculative positions, the optimal market positions become the traditional hedge in the futures market and no position in the options market. The DM is acting to minimize variance of the end-of-period income, which can be completely eliminated by taking the traditional hedge in the futures market. If either the futures market or options market is perceived to be biased, then the speculative components adjust the futures and options positions accordingly.

Opportunity Cost of MV Solution

The opportunity cost to the DM of using the MV market position instead of the EU position is the amount of additional income that must be given to the DM to provide the same level of expected utility as would be provided by using the EU market position. This money value, which we denote by V , is obtained by solving equation (13) for V .

$$(13) \quad EU(y(\hat{x}, \hat{z}) + V) = EU(y(x^*, z^*)),$$

where \hat{x} and \hat{z} are the MV market positions and x^* and z^* are the EU market positions.

Three dimensions of the MV and EU solutions are compared: (a) value of V , (b) correlation between x^* and \hat{x} , and (c) correlation between z^* and \hat{z} . For the DM studied here, the value of V is the only relevant measure of goodness of fit of MV to EU solutions. Large variations in options and futures positions are economically important only if they affect $E(U)$. It is possible that wide differences in the values of

the decision variables between the MV and EU frameworks do not make much difference in the level of the DM's expected utility.

Experimental Design

Equations (5) and (6) were used to derive optimal futures and options positions of a representative midwestern soybean producer who exhibits constant absolute risk aversion (CARA) subject to the preceding assumptions. These EU solutions were compared with corresponding MV solutions from (1). We could solve (6) for historical values of the market factors. But because commodity options have existed for a short time, this would provide a small sample of results. Consequently, we elected to solve (6) for a simulated set of market factors. To efficiently extract information from a given set of market factors, the factors were organized in a modified factorial design.

Values of the market factors were selected to represent conditions in midwestern soybean markets. The exogenous factors of the model were specified in terms of the levels of four "market factors," amount of output, and the level of risk aversion exhibited by the producer. The four market factors are: σ_p^2 , the variance of the soybean cash price; $B_f = P_f - \mu_p$, the perceived expected bias in the futures market; $B_o = E[P_e - P|P < P_e] - K$, the perceived expected bias in the options market; and $E_m = P_e - \mu_p$, the difference between the exercise price and the expected soybean cash price. Setting the exogenous factors of the model— σ_p^2 , μ_p , P_e , P_f , and k —in relation to these market factors ensured that various combinations of variable values in the design did not result in unrealistic specifications of market behavior.

The variance of average deflated November spot prices received by Iowa soybean producers during 1976–86 was \$1.08. We assigned values of σ_p^2 ranging from \$0.50 to \$1.50. From studies of pricing in futures markets (Gray; Just and Raussier; Conorella and Pollard; Telser; Cootner 1977a, b) and in options markets (Tucker, Whaley, Jordan et al., Luft and Fielitz), we conclude that, if any bias does exist in either futures or options markets, it is small and short-lived. The extreme values of each bias were set at $\pm\$0.04$. The extreme values of the difference between the exercise price and the expected spot price were set at $\pm\$0.10$.

The assigned values of the market factors and of Q and A were used in a central composite

experimental design (Khuri and Cornell). A factorial design is one in which all values of a given factor are combined with all levels of every other factor in the data set. A central composite design consists of a full factorial design for two levels of variable values called the upper and lower factorial levels and additional selected combinations of variable values around the two-level factorial design called the center and axial points. The intent of the central composite design is to capture much of the information of a full factorial design that uses more than two levels of each variable without the data requirements of a full three-level, or higher, factorial design. Table 1 presents the levels of the factors used in the design. The levels in this table were used in 77 different combinations to form a central composite design of $n = 77$ points.

To solve (6) we then applied MINTDF numerical integration (Kaylen and Preckel) and GQOPT/PC (Quandt and Goldfeld) numerical optimization to each combination of variable values to find the optimal futures and options positions, x^* and z^* .

Comparison of MV and EU Results

The MV results from (1) and the EU results from (6) were found for each combination of variables in the central composite design subject to the income functions in (7), (9), and (11). Thus, the MV solution could be directly compared to the EU solution for each model. The general behavioral characteristics of the EU results correspond to the economic behavior described by the MV model in the previous section. As the MV suggested, the EU maximizer hedges to reduce income variability and speculates according to any believed bias in the commodity markets adjusted by risk aversion and income variability.

The MV and EU results were identical for the CF model because the necessary and sufficient condition is met, which causes the linear MV model to produce the EU maximizing solution. As expected, the CO and CFO results for the MV model were different from those for the EU model because of the violation of sufficient conditions for equivalence between the MV and EU models. However, visual examination of the results of the MV and EU models suggests that the MV model does approximate the EU results. The twelve tabular pages of MV and EU solutions are not presented here but are available from the authors.

Table 1. Observation Levels in the Central Composite Design

Levels	Factors					
	E_m	σ^2	B_f	B_0	Q	A
	(\$)				(bu.)

Cash and Options

Results for the CO model are summarized in tables 2 and 3 and in the regression

$$z^* = 1,602 + 0.874 \hat{z} + e, \\ (313) \quad (0.015)$$

where $r^2 = 0.978$, the standard deviation of $e = 847$ bushels, and the values in parentheses are the standard errors of the estimated coefficients. The standard deviation of the errors amounted to only 17% of the smallest value of Q included in the experiment. An F -test rejected the null hypothesis that the intercept equalled zero and the slope equalled one at the 1% level. All values of \hat{z} and z^* were positive.

the relative absolute differences (RADs) between the EU and MV market positions: i.e., the absolute differences divided by 5,000 bushels, the size of a standard futures or options contract. The majority of the observations (57%) have a RAD of less than 15%, while the remaining observations are spread uniformly up to a RAD of 70%. The largest error in the MV solutions was 3,366 bushels, which amounted to 14.6% of the EU solution. Table 3 contains the frequency distribution of the opportunity costs of the MV market positions. The mean is around \$55 and the median is about \$13. The distribution is skewed with a range of nearly zero to \$350. The largest concentration of observations (64%) is in the \$0-\$20 range. Of the seventy-seven values of V , sixty-eight are less than 1¢ per bushel of Q . The largest value of V amounts of \$342, or slightly less than 2¢ per bushel.

Cash, Futures, and Options

Results for the CFO Model are summarized in tables 2 and 3 and in the simple regressions:

$$z^* = 51 + 1.68 \hat{z} + e, \quad (23) \quad (0.03)$$

where $r^2 = 0.978$, and the standard deviation of $e = 201$ bushels. An F -test rejected the hypothesis of a zero intercept and a unit slope at the 1% level.

$$x^* = -113 + 1.005 \hat{x} + e, \quad (153) \quad (0.010)$$

where $r^2 = 0.993$, and the standard deviation of $e = 412$ bushels. An F -test failed to reject the hypothesis of a zero intercept and a unit slope at the 40% level. The standard deviations of the errors in these two equations are less than 10% of the smallest value of Q included in the experiment. Some values of \hat{z} and z^* are positive, and some negative. Every value of z^* is less than 5,000 bushels (one options contract) and only eight exceed 2,500 bushels.

Table 2 shows that all of the RADs in the futures positions are less than 25% and 61% have a RAD of 5% or less. The RADs of the options positions are all less than 35%, and 53% of the observations have a RAD of less than 5%. The largest errors in \hat{x} and \hat{z} are 1,159 bushels and 1,628 bushels, which are 14% and 51% of the correct values x^* and z^* . The futures position has a relatively low percentage error because the traditional hedge is in the futures market in MV and EU models. The entire error in the options position is related to the speculative component. The resulting speculative error in the futures position for this particular observation was 61%.

Table 3 shows the opportunity cost to the DM of using the MV market positions instead of the EU positions has a mean of \$3.80 and a median of \$1.50. The distribution is skewed with all observations falling in the range \$0–\$18. The largest concentration of observations (53%) is in the \$0–\$2 range. The largest value of V is \$16.38, less than 0.2¢ per bushel of output.

Values of V and \hat{z} are positively correlated, as are values of V and A . As the size of the options position in the expected utility solution increases, the error in the standard MV solution goes up, and the value of the EU decision over the MV solution also rises. As the options position increases, the resulting income distribution deviates further from the normal distribution assumed by the MV model. Consequently,

the MV model results contain more error as the income distribution becomes "less normal." As the level of risk aversion rises, any deviation from the optimal solution is translated into a higher opportunity cost being attached to the MV solutions.

Comparative Statics: MV versus EU

The previous results show that the MV model can be used to produce results that approximate the solutions of the EU model. The analytical results of the MV model are also useful in providing insights into the numerical results generated by the EU model. For example, in EU solutions to the CO model the optimal options position is always greater than the output level. Using the analytical result from (10), it is easy to show that the variance of end-of-period income is minimized by taking an options position that is greater than the output level.

One test of the MV model's analytical usefulness is its ability to produce comparative static results consistent with those produced by the EU model. The comparative static results can be generated for the MV model directly by using equations (10) and (12). In some cases, the MV model comparative static results cannot be signed in general; e.g., $\partial x^*/\partial \sigma^2$ and $\partial z^*/\partial \sigma^2$ in the CFO strategy. However, the comparative static results for both the MV and EU models can be generated numerically over local regions. Table 4 presents the local comparative results over the region considered in this study. The comparative static results of the MV model are not always consistent with the EU model. In the CO strategy, there is some inconsistency between signs of $\partial x^*/\partial \sigma^2$ and $\partial x^*/\partial A$ across the various combinations of exogenous variables. In the CFO strategy there is some inconsistency in the two models between $\partial x^*/\partial E_m$ and $\partial z^*/\partial E_m$. The remaining comparative static results are consistent between the two models over the region considered.

The standard linear MV model used in this analysis is a special MV model. In general, the form of the MV function will not be known. It may be that the EU choices would be in the MV efficient sets generated by some alternative non-linear MV preference functions. In an alternative specification of the MV preference function, the differences between the two sets of results may be even smaller. Relaxing the assumptions such as CARA, normally distributed output price, no transactions costs, no basis un-

certainty, and no margin calls may also change some of the results. The impact of these assumptions is left for further study.

Conclusions and Implications

This study considered the approximating ability of the standard linear MV model for a DM with constant absolute risk aversion when the income distribution is truncated by the use of commodity options. The MV model was shown to provide analytical results useful in describing the general behavioral characteristics of the EU model. However, the comparative static results of the MV model were not always consistent with the comparative static results of the EU model. Thus, some care must be taken in interpreting the analytical results of the MV model when the sufficient conditions for expected utility equivalence are violated.

The MV model also produced empirical solutions that were close approximations of the EU model results. The opportunity costs of using the mean-variance solutions instead of the EU solutions were small. In the situations studied here, the payoff for performing the additional computations (the numerical integration and numerical optimization) instead of using the simpler MV solution is small. The MV model is robust to the particular violation of the assump-

tions that was studied here. These results will also be of interest to those concerned with modeling other decision-making problems under risk which are characterized by truncated probability distributions.

Evaluating Robust Regression Techniques for Detrending Crop Yield Data with Nonnormal Errors

Scott M. Swinton and Robert P. King

Although ordinary least squares is not efficient when errors are not distributed normally, it generates better crop yield trend coefficient estimates than six alternative robust regression methods. This is because of the econometric properties of an uninterrupted series independent variable as well as the level of skewness typical of corn yields. The evaluation covers actual farm-level corn yield series as well as a set of "contaminated" data series and one thousand sets of Monte Carlo yield series. Where an influential end-of-series outlier is suspected, the DFBETAS regression diagnostic statistic is recommended.

Key words: detrending, regression diagnostics, robust estimation, yield distributions.

When detrending farm-level crop yield time-series data, a series-end observation which lies far from the regression trend can exert undue influence on the trend coefficient. Until recently, the standard solution was to omit such an outlier from the data series. Now, however, a growing number of robust regression techniques make it possible to weight observations automatically so that outliers have reduced influence or none at all. This paper demonstrates that ordinary least squares (OLS) regression remains the preferred means of detrending time-series corn yield data when compared with a set of robust regression (RR) techniques. Conclusions are drawn from comparisons using (a) three sets of farm-level corn yields, (b) varying lengths of farm yield time series with an artificial series-end outlier, and (c) one thousand sets of randomly generated artificial corn yield data in time series of ten to twenty-five periods.

Crop yield time-series data are detrended in order to "remove" technology bias from estimates of the underlying probability distribution. Among other purposes, crop yield distributions are used in evaluating alternative crop plans and in analyses of crop insurance decisions. For

practical purposes, such distributions should be estimated by a method that (a) is simple, unbiased, and reasonably efficient, (b) requires only yield and time data, and (c) can accommodate short data series.

Detrending is generally accomplished by regressing observed values of the yield random variable on some measure of time using least squares methods. This approach yields maximum likelihood estimates under the assumption that the regression residuals are normally distributed. While this assumption may be suitable for some purposes, empirical tests have found that it often fails to hold for agronomic and farm-level crop yield data (Day, Nelson and Preckel). The negative skewness typical of corn yield probability density functions (pdf) implies that low extreme values are more likely to occur than if the pdf were normal. For example, a low, end-of-series outlier occurred in the Midwest in 1988 as a result of drought.

By down-weighting outlier observations, RR techniques may generate more efficient trend coefficient estimates when the data are not normally distributed. Such methods have been discussed extensively in the statistics literature during the past twenty years and are becoming increasingly available to applied economists in econometric software packages. However, it will be shown that they do not necessarily offer coefficient estimates that differ significantly from OLS estimates, even when errors are not normally distributed. This paper will (a) illustrate

cases in which several robust regression methods on an equation having nonnormal errors fail to give coefficient estimates significantly different from OLS and (b) demonstrate how regression diagnostics can identify conditions under which RR is a useful alternative to OLS for detrending time-series data.

Nonnormal Errors and Robust Regression

In the standard linear model, with n observations and k regressors,

$$Y = X\beta + u,$$

where Y is an $(n \times 1)$ dependent variable vector, X is an $(n \times k)$ matrix of k independent variables, β is a $(k \times 1)$ coefficient vector, and u is an $(n \times 1)$ disturbance vector, OLS will yield maximum likelihood estimates of model parameters when $u \sim N(0, \sigma^2)$. When u is not distributed normally, the OLS coefficient estimator, b , is still the best linear unbiased estimator, and the OLS variance estimator, s^2 , is still unbiased and consistent. However, neither b nor s^2 is efficient or asymptotically efficient, since the maximum likelihood estimator is nonlinear (Judge et al., p. 888).

Because OLS minimizes the sum of squared errors, large residuals or "outliers" can exert considerable influence on parameter estimates. Robust regression methods give less weight than OLS to observations whose dependent variable deviates far from its expected value. They can be viewed as automated means of reducing outlier influence and are classified by their approach to controlling influential outliers. M -estimators employ maximum-likelihood techniques for finding regression coefficients that minimize some function of the regression residuals, typically one that gives less weight than OLS to residuals large in absolute value. Linear combinations of order statistics, or L -estimators, calculate regression coefficients for quantiles of the residuals resulting from a regression model and then combine them with specified weights.

Both classes of RR methods were used to detrend three corn yield time series after discovering that the OLS residuals were negatively skewed in two of the series. The structural model for each farm took the simple, linear form:

$$CORN\text{YLD} = \beta_0 + \beta_1 \cdot \text{YEAR} + u,$$

where $CORN\text{YLD}$ denotes the corn grain yield in bushels per acre, and YEAR is the corresponding year. The three series came from farms

in Jackson County, Minnesota, having 22 to 43 annual yield observations ending between 1985 and 1987. Due to the negative skewness of the OLS residuals from farms A and B, it was suspected that outliers might be distorting the OLS coefficient estimates. Six RR methods discussed in Judge et al. were used to reestimate the trend parameter: the multivariate t , which is an M -estimator, and five L -estimators, the least absolute error (LAE), trimmed mean ($TRIM$), five quantity-weighted regression quantile ($FIVEQUAN$), the Gastwirth weighted regression quantile ($GASTWIRTH$), and Tukey tri-mean weighted regression quantile ($TUKEY$) procedures, available in SHAZAM (White, Shirley, and Horsman).

As summarized in table 1, all estimates of the coefficient on YEAR lie within one OLS standard error of the OLS estimate. For all three farms, coefficient estimates with RR are not significantly different from OLS, despite (1) a disproportionately large number of negative residuals for farms A and B, (2) negative summed residuals on all three farms for all RR methods used, and (3) a relatively large OLS standard error for farm C.

Regression Diagnostics

Three regression diagnostic statistics are particularly helpful in gauging the influence of an ob-

Table 1. Coefficient Estimates Compared for YEAR Variable in the Linear Model: OLS versus Six Robust Regression Methods

Regression Method	Farm A	Farm B	Farm C

* This L -estimate could not be computed due to small sample size relative to the size of the desired trim quantile.

servation upon a coefficient estimate: (a) h_i , the measure of potential leverage by individual observations on the independent variables to influence the regression (b) e_i^* , the "studentized" residual, a measure of what constitutes an influential outlier, and (c) $DFBETAS$, a newer diagnostic that measures the impact on a given coefficient of a given observation (Belsley, Kuh, and Welsch).

The potential influence, or leverage, of an observation, h_i (Belsley, Kuh, and Welsch; Judge et al.; Weisberg), is defined as follows:

$$h_i = x_i'(X'X)^{-1}x_i,$$

where x_i is an observation on the independent variable(s) and X is the matrix of all observations on the independent variable(s). Key characteristics of h_i are (a) it always lies between zero and one, (b) the h_i 's sum to k , the number of regressors, and (c) h_i is a function of the independent variables only. As observations on the independent variables, x_i , get farther from the sample mean, they become potentially more influential, and h_i grows larger. Since the average value of h_i is k/n , a conservative rule of thumb for identifying observations with high leverage is $h_i \geq 3k/n$ (Judge et al., p. 893).

A widely employed, reliable measure of whether an extreme residual is indeed a statistical outlier is the "studentized" residual (Belsley, Kuh, and Welsch; Weisberg), e_i^* ,

$$e_i^* = \frac{e_i}{s(i)^*(1 - h_i)^{.5}},$$

where e_i is the residual corresponding to the i th observation and $s(i)$ denotes the sample standard error of the estimate calculated omitting the i th observation. As is clear from its composition, e_i^* will be large if one or more of the following conditions holds: (a) e_i is large, (b) h_i is large, or (c) $s(i)$ is small. The studentized residual follows the central t -distribution with $n-k$ degrees of freedom. However, since it describes a residual which represents one of many "draws" from the distribution, the appropriate test statistic is the Bonferroni t -value, which tests the hypothesis that the residual occurs with a/n probability, where a is the probability of mistakenly rejecting the hypothesis that e_i is an outlier and n is the number of observations in the sample (Weisberg, p. 116).

Belsley, Kuh, and Welsch have developed a statistic called $DFBETAS$ to measure the influence that an observation is likely to have on the regression coefficient. It measures the difference between estimates for the j th coefficient

with (b_j) and without ($b_j(i)$) the i th observation, as standardized by the coefficient standard error:

$$DFBETAS_{ij} = \frac{b_j - b_j(i)}{s(i)[(X'X)_{jj}^{-1}]^{.5}},$$

where $(X'X)_{jj}$ denotes the j th diagonal element of the $(X'X)$ projection matrix. Belsley, Kuh, and Welsch demonstrate that $DFBETAS$ decreases with sample size at a rate proportionate to $n^{-.5}$. Hence, they recommend a "size-adjusted cutoff" of $|DFBETAS| > 2/(n^{.5})$ (p. 28).

Diagnosis of Residuals from Regressions to Detrend Time Series

In a regression to detrend an uninterrupted time series, the time measure increases by a single unit from one observation to the next. This property has distinct consequences for regression diagnostics.

First, the measure of potential leverage, h_i , cannot become very large because there are no x_i values far from the mass of x_i 's. The h_i values are greatest at the beginning and end of the series, following a symmetric U-shaped pattern. Since the h_i 's sum to the number of regressors, in a simple regression they sum to 2. As the number of sequential observations increases, the potential leverage of any one decreases. For uninterrupted time series, h_i values will be the same for any two samples of the same size, and it can be shown that none will exceed the conservative Judge et al. cutoff value of $3k/n$ (Swinton and King, p. 9).

Barring a high h_i value, it is clear that an externally studentized residual can become "large" only if (a) $s(i)$ is small, or (b) e_i is large. However, given the routine variability of much agricultural data, $s(i)$ and e_i do not often reach orders of magnitude great enough for e_i^* to become significant. Furthermore, while any dependent variable outlier may influence the intercept coefficient, only those corresponding to the beginning or ending of the time series will have a marked effect on the slope coefficient.

The most reliable regression diagnostic for revealing the influence of an observation on coefficient estimates is $DFBETAS$. This becomes especially evident in a test of regression diagnostics and robust methods on a "contaminated" data set. A set of eight corn yield data series of five to forty years, all ending in 1984 from the same southwest Minnesota farm, were modified by replacing the 1984 value with an artificial yield observation of 72.7 bushels per acre, three stan-

dard errors below the expected yield of 122.5 bushels per acre. The test was conceived to model the effect that might be expected from low yields caused by severe drought. Table 2 compares regression diagnostics from the 1984 observation and presents estimates of the coefficient on *YEAR*. Of the three regression diagnostic measures, only *DFBETAS* signaled a potential problem with the 1984 observation. The h_i values all remained predictably below the size-adjusted cutoff value. The studentized residuals were small for small samples because the large outlier significantly influenced the regression, reducing e_i and increasing $s(i)$. None of the studentized residuals exceeded its Bonferroni critical t -value.

Although robust regression has been recommended as a pre-diagnostic technique (Weisberg, p. 253), table 2 demonstrates that robust methods are not foolproof. Only the 20% trimmed mean regression procedure generated coefficients consistently within two coefficient standard errors of the OLS estimate on the uncontaminated sample [$1.88 \pm 2(0.23)$]. However, in *SHAZAM*, trimmed mean least squares (TLS) estimates cannot be computed for sample sizes too small to allow at least three observations in the quantiles to be cut from each tail. The least absolute errors (LAE) estimator performed very poorly, and the estimator following the multivariate t -distribution with one degree of freedom

did no better than the OLS estimator. Of the three RR estimators, TLS performed best, generating coefficient estimates closer to the uncontaminated OLS estimates than OLS for $n < 25$. However, TLS could not be computed for the five observation case. By contrast, since *DFBETAS* revealed that 1984 was a potentially influential observation in every case, its use would have permitted obtaining better OLS estimates by deleting the 1984 observation.

OLS versus Trimmed Least Squares: A Monte Carlo Experiment

In the "contaminated" sample examined above, TLS outperformed both OLS and the other RR methods tested in small samples. A Monte Carlo experiment was conducted to validate these results on the kind of error distributions encountered in detrending farm-level corn yields. Based on the finding of Nelson and Preckel that Iowa farm-level corn yields follow a negatively skewed beta distribution, four sets of time-series data were generated for yields with a trend of 2 bushels per year and a random error drawn from three different beta distributions and one normal distribution, all with mean 0. Since the beta distribution is defined on the interval [0, 1], the generated beta random variates were centered

Table 2. Comparison of Regression Diagnostics and Robust Regression Methods on Corn Grain Yield Detrending Regressions for Farm A with a "Contaminated" 1984 Observation

Number of Observations	Year Series	Studentized Residual for 1984 ^a	<i>DFBETAS</i>	Coefficient on <i>YEAR</i>			
				OLS	LAE	Mt = 1 ^b	TRIM = .2
5	1980-84	-1.02	-1.02 ⁺	-14.32 (5.24) ^d		-17.16

30	1955-84	-2.68	-0.88 ⁺	1.91* (0.41)	2.51	2.23*	2.07*
35	1950-84	-2.61	-0.79 ⁺	1.84* (0.32)	2.51	2.13*	2.22*
40	1945-84	-2.63	-0.74 ⁺	1.73* (0.25)	1.96*	1.92*	1.82*

Note: The "contaminated" 1984 observation was three standard errors of estimate below the expected value for that year.

^a Bonferroni critical values exceeded 3.48 in all cases.

^b Denotes multivariate t -distribution with 1 degree of freedom.

^c Plus indicates *DFBETAS* value exceeds size adjusted cutoff of $2/(n^5)$.

^d Standard error in parentheses.

^e Asterisk indicates coefficient estimate lies within two coefficient standard errors of uncontaminated OLS estimate for 1945-84, $1.88 \pm 2(0.23)$.

Table 3. Parameters of the Distributions from Which Random Errors Were Generated

Distribution	Minimum	Maximum	Mean	Standard Deviation
Beta (3, 3)	-50	50	0	18.90
Beta (5, 3)	-62.5	37.5	0	16.14
Beta (15, 3)	-83.3	16.7	0	8.55
Normal (0, 625)	-infinity	infinity	0	25.00

on 0 by subtracting the mean and then scaled over a range of 100. Parameters for the beta distributions were (3, 3), a symmetric distribution; (5, 3), a negatively skewed distribution in the range encountered by Nelson and Preckel; and

(15, 3), a still more negatively skewed distribution. Random errors were also generated from a normal (0, 625) distribution, for which 95% of the distribution falls in the 100-bushel range of the scaled beta (3, 3) distribution. Parameters of distributions from which the random errors were generated are presented in table 3.

Key results from 1,000 regressions using both OLS and trimmed least squares (trim proportion = .2) on randomly generated data from the four distributions reveal that under OLS, trend coefficient estimate ranges are narrower and standard deviations are smaller in all cases, as shown in table 4. In most cases, the sample mean of the trend coefficient estimates is as close or closer to the true value of 2 under OLS as under TLS for data from all four distributions. OLS gen-

erated the more accurate mean coefficient estimate in all instances where samples had fewer than twenty observations; these are precisely the cases in which analysts are most concerned about outlier bias. This is probably due to the fact that after trimming, TLS had few observations to work with when data sets were small. An unrelated, but significant, advantage of OLS is that it generated coefficient estimates for every data set. The regression quantiles used for L -estimators are calculated as solutions to a linear programming problem, using the approach developed by Koenker and Bassett. However, for small data sets, there may not be a feasible solution. TLS could not reach a solution in over one-third of the regressions using ten observations, and even when twenty-five observations were available, TLS still failed to reach a solution roughly one-twentieth of the time.

Concluding Comments

This analysis shows that many robust techniques fail to give more reliable coefficient estimates than OLS in a simple detrending regression when an extreme value of the dependent variable lies at the end of a time series. For this class of problem, influential outliers can occur if and only if (a) the standard error of estimate omitting the i th observation is very small and/or (b) the i th residual is very large. However, these conditions rarely occur under probability distributions typical of corn yields. A Monte Carlo study found OLS to generate more accurate coefficient estimates than trimmed least squares. It is concluded that for yield detrending problems, OLS

provides more consistently accurate coefficient estimates than the robust regression alternatives tested. When an extreme outlier is suspected, the *DFBETAS* regression diagnostic statistic provides the best measure of whether its influence is strong enough to merit eliminating that observation from the data set.

Cointegration Tests and Spatial Price Linkages in Regional Cattle Markets

Barry K. Goodwin and Ted C. Schroeder

This analysis empirically evaluates spatial linkages in regional cattle markets using cointegration tests of regional price series. Several markets were not cointegrated over the 1980 through 1987 period. However, significant increases in cointegration of several regional livestock markets are observed through the 1980s. The increased cointegration parallels significant structural changes in the livestock industry. A formal analysis of market characteristics reveals that distances between markets, industry concentration ratios, market volumes, and market types have significant influences on cointegration relationships between markets.

Key words: cattle markets, cointegration tests, spatial market linkages.

Spatial price behavior in regional cattle markets is an important indicator of overall market performance. Markets that are not integrated may convey inaccurate price information that might distort producer marketing decisions and contribute to inefficient product movements. In recent years, cattle markets have undergone dramatic regional shifts in production, slaughtering, and processing (Ward). However, some regional markets, particularly those declining in relative volume and importance, may not react efficiently to evolving information (Tomek). Previous studies have examined lead-lag relationships among regional cattle prices (Bailey and Brorsen; Koontz, Garcia, and Hudson; Schroeder and Goodwin). Results generally indicate that prices in the western Corn Belt region tend to lead prices in other markets. With the disparity in market power between cattle producers and slaughter cattle procurers, cattle buyers have the potential to influence regional prices. In addition, with declining relative cattle sales volumes in some regions and increasing volumes in other locations, regional prices could diverge because of poor information flows across regions. In the presence of these influences, price changes across different regions may not fully reflect relevant economic conditions.

The objective of this paper is to empirically evaluate cointegration and spatial price linkages for regional slaughter cattle markets and to determine the impacts on cointegration of several market characteristics. Cointegration tests are developed and applied to spatial price relationships among eleven regional slaughter cattle markets. Bootstrapping regressions are then utilized to evaluate the influences of several variables on cointegration.

Spatial Price Linkages in Regional Markets

Regional markets may be linked through the competitive profit-seeking activities of commodity arbitrageurs. Arbitrage activities commonly involve the purchase of commodities in regional markets where the price is relatively low and the subsequent resale in markets where the commodity is dear. Regional arbitrage will ensure that a unique equilibrium is reached where local prices in alternative markets differ by no more than transportation and transactions costs. In this case, the expected returns to regional commodity price speculation are forced to zero and markets are spatially integrated. However, Takayama and Judge have noted that this sort of direct market linkage requires the assumption that all buyers and sellers are located at discrete points with no intraregional transportation costs.

Alternatively, regional markets may be linked through an oligopolistic (or oligopsonistic) interdependence whereby firms compete only within a limited service area (Benson and Fa-

The authors are assistant professors, Department of Agricultural Economics, Kansas State University.

The helpful comments of Andrew Barkley, David A. Bessler, Merle Faminow, Philip Garcia, and Zach Lea are gratefully acknowledged.

minow). In this case, transportation costs which increase as trade distances rise necessarily limit the area relevant to interfirm competition. According to Faminow and Benson, this situation may result in market linkages that follow a non-competitive basing-point pricing system which is maintained through an organized oligopoly arrangement. Under basing-point pricing, oligopoly cooperation among firms leads to the establishment of a base price at a central location, and the delivered price to any buyer location is the base price plus transportation costs (Scherer). Under a basing-point pricing arrangement, markets will be spatially integrated as the collusive arrangement implies perfectly linked prices at all locations. Faminow and Benson note that this version of spatial integration does not depend upon the assumption that intraregional transportation costs are negligible.

Ardeni has argued that the conventional approaches to testing spatial integration may misrepresent or ignore the time-series properties of regional price data series. Such properties may have important implications for the spatial linkages of a market. In particular, ignoring serial correlation in empirical tests of spatial market integration may result in tests which are vulnerable to inferential inconsistencies and biases. Furthermore, analyses making use of price differentials may suffer because such differencing transformations and filters are ad hoc in nature and may be inappropriate for a given price series.

Alternative procedures for evaluating spatial market linkages have been developed within the framework of cointegration tests by Granger, Engle and Granger, and Engle and Yoo. The general cointegration procedures appeal to the fact that deviations from equilibrium conditions for two economic variables, which are nonstationary when taken by themselves, should be stationary. The intuition is that economic forces should prohibit persistent long-run deviations from equilibrium conditions, although significant short-run deviations may be observed. An important implication is that, while individual economic variables such as prices may wander extensively, certain pairs of such variables should not diverge from one another in the long run. A recent application of cointegration testing to spatial price relationships can be found in Ardeni.

Cointegration tests provide an especially suitable framework in which to consider long-run price relationships among regional cattle markets. Weekly prices in these markets are highly

variable and often possess significant trends, suggesting the potential for nonstationarity in long-run price series. However, efficient arbitrage and basing-point pricing conditions in regional markets suggest that regional prices in alternative markets should not diverge from one another.¹

Cointegration Tests of Spatial Price Relationships

Consider two series of economic variables; y_t and x_t . Each series by itself is nonstationary and requires a single differencing transformation to produce a stationary series. However, a linear combination of the two series,

$$(1) \quad y_t - \alpha - \beta x_t = e_t,$$

produces a residual series e_t which is stationary. In this case, the series y_t and x_t are said to be cointegrated. More precisely, y_t and x_t are cointegrated of order (1,1) with a cointegrating parameter of β and the linear relationship given by (1) is called the cointegrating regression. A series is integrated of order (d) if it must be differenced d times to obtain stationarity. Two series are cointegrated of order (d,b) if the individual series are integrated of order (d) and their linear combination is integrated of order ($d-b$) (Engle and Granger).

Spatial market integration, brought about by commodity arbitrage or collusive basing-point pricing, necessarily implies a unique long-run equilibrium relationship in which deviations from regional price parity are forced to zero. Such an equilibrium need not require that deviations from equilibrium are always zero or even serially uncorrelated. Delivery lags between spatial markets and other impediments to regional trade and arbitrage activities might result in the short-run persistence of deviations from the steady-state equilibrium. Similarly, incomplete basing-point pricing behavior as described by Faminow and Benson might result in short-run deviations from equilibrium conditions. However, spatial integration will require that deviations from eco-

¹ Granger (p. 218) notes that, for a pair of prices from speculative markets, cointegration implies a lack of efficiency because prices should incorporate all available information. However, this result requires instantaneous arbitrage, which is necessarily precluded by spatial linkages that include delivery lags. With such linkages, a spatial dimension to efficiency will require that prices not wander arbitrarily far apart in the long run. In this light, cointegration may imply a form of spatial efficiency for regional market linkages.

nomic equilibrium conditions have a stable mean of zero. In terms of cointegration, this condition implies that two spatially separated markets are spatially linked and interdependent if regional prices can be used to form a cointegrating regression representative of a spatial price parity equilibrium condition.

Conventional analyses of spatial market integration typically posit a parity relationship between markets in which price changes in one market are reflected by equilibrating changes to prices in alternative markets. Such an equilibrium relationship can be written as²

$$(2) \quad p_t^1 - \alpha - \beta p_t^2 = u_t,$$

where p_t^1 and p_t^2 represent logarithmic commodity prices in two alternative regional markets. The residual error term u_t represents proportional deviations from price parity. If the logarithmic price series are nonstationary but their combination in (2) produces a stationary series for u_t , the series are cointegrated of order (1,1) with a cointegration parameter β . This condition suggests a natural empirical approach for evaluating the spatial price linkages between a pair of regional markets through the use of OLS estimation procedures in connection with the cointegration analysis techniques. Perfect spatial integration will be offered empirical support for a pair of regional markets if the regional price series are cointegrated with a cointegrating parameter approximately equal to one.³

The existence of perfectly spatially integrated markets (where price changes in one market are fully reflected by equilibrating changes in alternative markets) necessarily requires that the estimated slope parameter of the cointegrating regression, $\hat{\beta}$, have a value of one. However, because the price series p_t^1 and p_t^2 are nonstationary in a cointegrated system, conventional statistical procedures cannot be used to provide reliable hypothesis tests regarding the value of β . In particular, while the empirical estimate of the cointegrating parameter is consistent, the es-

timated standard error of the cointegrating parameter is not consistent. In this light, it is impossible to conduct explicit significance tests for the estimated cointegrating parameter. Engle and Granger discuss the properties of OLS estimates of cointegrating regression parameters in detail.

Engle and Granger have proposed a two-step procedure for evaluating the cointegrating properties of a concurrent pair of nonstationary economic time series. The first stage involves estimating the parameters of the cointegrating regression representative of the presupposed economic equilibrium condition by using standard OLS regression techniques. Estimates of the parameters of the cointegrating regression can then be used to calculate estimates of the residual errors, \hat{e}_t , where

$$(3) \quad \hat{e}_t = y_t - \hat{\alpha} - \hat{\beta}x_t.$$

Upon obtaining estimates of the first-stage residual errors, Engle and Granger propose seven different tests for cointegration. They also provide critical values for a sample of 100 observations based upon the results of Monte Carlo simulations for each proposed test statistic. Each test has no cointegration as its null hypothesis. Rejections of the tests which follow lend support for cointegration in the regional markets in this analysis. The existence of a variety of tests follows from the usual problems associated with unit root tests⁴ and parameters which are unidentified under the null hypothesis, and because the power of any individual test may vary across actual empirical circumstances (Engle and Granger).

The first test for cointegration suggested by Engle and Granger involves the use of the standard Durbin-Watson test statistic from the first-stage OLS estimate of the cointegrating regression ($CRDW$):

$$(4) \quad CRDW = \left(\sum_{t=2}^T (\hat{e}_t - \hat{e}_{t-1})^2 \right) / \left(\sum_{t=1}^T \hat{e}_t^2 \right).$$

The null hypothesis of no cointegration is rejected for values of $CRDW$ which are significantly different from zero. The $CRDW$ statistic is approximately equal to $2 - 2\hat{\rho}$, where $\hat{\rho}$ is the estimated autoregressive parameter for the residual errors from the cointegrating regression (Judge et al.). In this light, Engle and Granger's

² The parameter α in (2) might be considered a proportional shifter which reflects the costs of interregional trade. Such costs might include interstate tariffs, risk premiums, and transportation charges.

³ While perfect spatial integration requires that price changes in one regional market are fully matched in other markets, cointegration requires only that prices not drift arbitrarily far apart in the long run. We would not necessarily expect efficiently linked markets to have $\beta = 1$. Prices in two efficiently linked markets could vary in a nonsynchronous manner within the band created by transactions costs and thus not imply perfect integration (i.e., $\beta \neq 1$). In addition, quality differences across regions might also bring about a $\beta \neq 1$ without implying inefficient spatial linkages. However, cointegration should be supported in both cases.

⁴ In particular, unit-root test statistics must be constructed using nonstandard distributions, using parameters which are unidentified under the null hypothesis.

first proposed test is analogous to a test of whether $\hat{\rho}$ is significantly different from one.

The second and third cointegration tests proposed by Engle and Granger utilize Dickey-Fuller (1979, 1981) type regressions to consider whether the autoregressive parameter for the estimated residuals from the cointegrating regression is significantly different from one. If there is a unit root, then the two series are not cointegrated. The first Dickey-Fuller-type test depends on estimates of

$$(5) \quad \Delta \hat{e}_t = -\phi \hat{e}_{t-1} + \epsilon_t,$$

where \hat{e}_t is the first-stage estimate of the residual from the cointegrating regression and Δ implies the first difference. A test statistic (DF) is constructed from the ratio of the estimated ϕ to its standard error (a t -ratio). The null hypothesis of no cointegration is rejected for values of ϕ which are significantly different from zero. This is verified by calculated values of DF which exceed the tabulated critical values determined by Engle and Granger. The second Dickey-Fuller type test is analogous to the first except that it contains p lagged values of the differenced residual errors:

$$(6) \quad \Delta \hat{e}_t = -\phi \hat{e}_{t-1} + \theta_1 \Delta \hat{e}_{t-1} + \dots + \theta_p \Delta \hat{e}_{t-p} + \epsilon_t.$$

The addition of the lagged differences ensures that the second-stage residuals of the augmented Dickey-Fuller regression, ϵ_t , are serially uncorrelated. A test statistic (the ADF) is constructed from this regression by again taking the t -ratio for the estimate of ϕ .

The fourth and fifth cointegration tests proposed by Engle and Granger involve the estimation of a vector error correction mechanism for the cointegrating regression:

$$(7) \quad \begin{aligned} \Delta y_t &= \beta_1 \hat{e}_{t-1} + \epsilon_{1t}, \text{ and} \\ \Delta x_t &= \beta_2 \hat{e}_{t-1} + \gamma \Delta y_t + \epsilon_{2t}. \end{aligned}$$

A test of no cointegration is based on the joint significance of the error correction coefficients β_1 and β_2 . This test exploits the fact that a cointegrated set of variables can be equivalently expressed as an error correction model in the form of (7). The intuition behind such error-correcting mechanisms lies in the expectation that agents will react to preceding deviations from equilibrium conditions, thus bringing about responses in the current values of the cointegrated variables, y_t and x_t . A test statistic ($RVAR$) is

calculated by taking the sum of the squared t -ratios of β_1 and β_2 . If β_1 and β_2 are jointly different from zero, the null hypothesis of no cointegration is rejected. The fifth cointegration test statistic (the $ARVAR$) is constructed in an analogous manner to the fourth from an augmented system with added lagged values of differences of the economic variables (Δy_t and Δx_t) to ensure white noise in the error terms of the vector autoregressive system.

The two preceding vector autoregression cointegration tests are conditional on the estimates from the cointegrating regression. The final two cointegration tests relax this restriction by estimating a vector autoregression which is not constrained to satisfy the cointegration constraints. The first system regresses differenced values of each of the hypothesized cointegrated variables on the levels of the variables:

$$(8) \quad \Delta y_t = \theta_1 y_{t-1} + \theta_2 x_{t-1} + c_1 + \epsilon_{1t}, \text{ and}$$

$$\Delta x_t = \theta_3 y_{t-1} + \theta_4 x_{t-1} + \gamma \Delta y_t + c_2 + \epsilon_{2t}.$$

The null hypothesis of no cointegration is rejected if parameters θ_1 and θ_2 of the first equation and θ_3 and θ_4 of the second equation are jointly, significantly different from zero. A failure to reject the null hypothesis indicates the lack of a significant relationship between current changes and past values of the economic variables. It implies a general failure of cointegration between the variables. A convenient test statistic (the $UVAR$) can be constructed by taking twice the sum of the F -tests of joint significance of the θ_i 's in each equation. The final cointegration test statistic (the $AUVAR$) is constructed in an analogous manner from an augmented system with additional p -lags of Δy_t and Δx_t added to ensure serially uncorrelated residuals.

Detailed discussions about these tests are presented in Engle and Granger. Alternative empirical circumstances could alter the power and conclusions of any individual test. Thus, to strengthen the confidence associated with the tests, our application utilizes each of the seven test statistics. In many comparisons of interrelated economic time series, economic theory provides little guidance as to which variable corresponds to x_t and which corresponds to y_t in the cointegration tests. This is certainly true for the bivariate comparisons of alternative regional price series in this study. Because misspecification could bias the results of the cointegration tests, each test is performed twice, with the designations reversed for the second test.

Factors Affecting Cointegration and Spatial Arbitrage Opportunities

The cointegration tests discussed above provide evidence about the linkages among prices at different markets. In this light, cointegration is not an absolute test but is a matter of degree. For a given time period, two markets' price series which move together will be highly cointegrated. Conversely, two markets' price series which tend to diverge from each other for extended periods will have low cointegration. Of interest are the factors that influence the degree of cointegration among regional fed cattle markets. Greater understanding of these factors allows more conclusive statements regarding spatial price relationships among these markets.

A primary factor affecting cointegration is an agent's cost and risk associated with trade between markets (Buccola 1989). The greater are the risks and costs of trade between two markets, the less likely they are to be cointegrated. In general, all markets are linked with one another through intermediary markets. However, these linkages weaken as the distance between markets increases. Mulligan and Fik have formalized this distance relationship in an analytical model of spatial competition. Distance between markets is used as a proxy of costs and as a contributing factor toward risk in this study. The costs associated with trade between spatially separated cattle markets will be directly related to the road distance between the markets. Trucking costs and shrinkage may prevent perfect correlation among prices in spatially separated markets and may even cause prices to diverge for periods of time, even if these markets are operating efficiently. In addition, risks associated with higher death losses and changing relative prices between markets during shipping and delivery lags increase as distance between markets increases. Thus, distance between markets is expected to have a negative influence on the level of cointegration.

A second factor affecting the risk of arbitrage between markets is the amount of market information reflected in prices at a particular market. Liquid terminal markets, for example, have a more complete set of market information in each trade than do decentralized direct trade markets (Lang and Rosa). Price discovery in terminal markets occurs by the interaction of several well-informed packer buyers and commission selling agents. Conversely, direct trades often occur between a single buyer and a single (often less informed) seller. Buccola (1985) finds that cen-

tralized market prices are in general more efficient than decentralized market prices. Thus, with all else constant, terminal markets may be more highly cointegrated than are direct trade markets.

Market volume also may influence trade activity across market areas. Low-volume markets have a higher potential for exhibiting unwarranted price behavior (Tomek). However, the concentration of cattle feeding and alternate market outlets are arguably more important influences on regional trade activities than the absolute volume traded at a particular location. Thus, the concentration of cattle feeding in a market's region could influence the degree of cointegration. However, the influence of market volume on cointegration is not clear. The thin market issue implies that markets with higher volume are more highly cointegrated. However, market regions with higher concentrations of cattle feeding may also operate independently of markets in other regions because of short-term local market forces. Examples are pressures to operate local packing plants at capacity and evolving local information pertinent to price. Thus, the relationship between market volume and cointegration is ambiguous.

A final factor which may influence spatial cointegration in regional cattle markets is packer concentration. Carlton has shown that price stability increases with increasing concentration in several industrial markets. With increased concentration of cattle packers operating across several markets, cointegration of these markets could increase, especially if the highly concentrated firms compete in the same market regions, as occurs in slaughter cattle markets (Ward). By operating plants in several spatially separated markets, the firms reduce spatial transactions costs and uncertainty about market outlets for cattle shipped from one region to another. In addition, increased concentration may facilitate collusive pricing behavior among meatpackers. In particular, discriminatory basing-point pricing practices may result from increased industry concentration. Such behavior would strengthen spatial price linkages.

The seven cointegration test statistics provide formal tests of cointegration which differ with respect to their statistical power under alternative empirical situations. The effects of several market characteristics can be considered through the following model:

$$(9) \quad TS_{ikt}^j = \beta_0 + \beta_1 \text{Type}_i + \beta_2 CR_i + \beta_3 \text{Volume}_{ikt} + \beta_4 \text{Distance}_{ik} + e_{ikt}^j$$

for $i = 1, \dots, 10$; $j = 1, \dots, 7$; and $t = 1, \dots, T$; where TS_{ikt}^j represents the j th cointegration test statistic between markets i and k ($j = 1, \dots, 7$ for $CRDW, \dots, AUVAR$), $Type_i$ is an indicator variable equal to one if market i is direct and zero if a terminal market, CR_t is the four-firm beef slaughter concentration ratio in time t , $Volume_{ikt}$ is slaughter cattle volume in market i 's region relative to that of market k in time t , $Distance_{ik}$ is miles between market i and market k , and e_{ikt}^j is a residual error. Given the preceding discussion, the parameters of equation (9) are hypothesized to have the following signs: $\beta_1 < 0$, $\beta_2 > 0$, β_3 is uncertain, and $\beta_4 < 0$.

Data Description

Weekly price series for Choice, yield grade 2–4, 900–1,100 pound slaughter steers were assembled for eleven U.S. regional markets over the period covering January 1980 through September 1987, yielding a total of 400 weekly observations. The data were collected from the Chicago Mercantile Exchange and from the U.S. Department of Agriculture's *Livestock, Meat, and Wool Market News*. Prices were collected for direct cattle markets of California, Colorado, Illinois, Iowa–Southern Minnesota, Western Kansas, Eastern Nebraska, and Texas Panhandle. Price data were also obtained for terminal markets of Lancaster, Pennsylvania; Omaha, Nebraska; South St. Paul, Minnesota; and Sioux City, Iowa.

These markets include a geographic dispersion of markets which differ in pricing methods (direct versus terminal) and cattle volumes. The markets include those with the largest cattle volumes as well as several small volume markets.

Several of the price series had a small number of missing observations. The total number of missing prices was twenty-six (less than 0.6% of the total data points). The missing prices were proxied by the predicted values from a regression of the series on the 1,100- to 1,300-pound steer price at the same location during the same week.

Empirical Results for Cointegration Tests

Applications of the empirical tests of cointegration are constrained because the relevant critical values have been defined by Engle and Granger

only for samples of 100 observations.⁵ In this light, our applications are to four subsets of the overall data consisting of 100 observations each, which roughly correspond to the two-year periods 1980–1981, 1982–1983, 1984–1985, and 1986–1987. This approach is consistent with the test requirements and allows us to test the impact of changes in industry concentration and relative cattle feeding concentrations across regions. Ward has noted that changes in marketing patterns and industry concentration ratios may have had important structural impacts on the market performance of the beef industry.⁶

The empirical tests of cointegration must be preceded by a test of nonstationarity for the individual economic variables under consideration. Granger suggests using the unit root test developed by Dickey and Fuller (1979, 1981). The test is generated from the following regression:

$$(10) \quad \Delta y_t = \alpha + \phi y_{t-1} + \sum_{i=1}^p \theta_i \Delta y_{t-i} + \epsilon_t,$$

where p is large enough to ensure that the residual ϵ_t is empirical white noise. The Dickey-Fuller test statistic is the ratio of $\hat{\phi}$ to its standard error obtained from OLS regression. The null hypothesis of a unit root is rejected for values of $\hat{\phi}$ which are negative and significantly different from zero using the significance levels calculated by Dickey and Fuller (1981).

The Dickey-Fuller unit root test, based on equation (10), was utilized to test the null hypothesis of a unit root in each of the price series for each period. The test utilized lag orders selected by the minimum value of Akaike's final prediction error (*FPE*). The results supported the presence of a unit root in every case and thus indicate nonstationarity in each of the price series.⁷

Cointegration regressions of the form given by equation (2) were estimated using ordinary

⁵ Engle and Yoo have further investigated properties of the *CRDW*, *DF*, and *ADF* test statistics for alternative sample sizes. Their results provide critical values for the *CRDW*, *DF*, and *ADF* for samples of $n = 200$.

⁶ Ward (pp. 14–15) notes that the four-firm concentration ratio in the steer and heifer slaughtering industry has gone from 39% in 1980 to over 64% in 1986 (see table 3). Increased industry concentration ratios have raised three important concerns. First, increased market power by processors may depress the prices paid for livestock. Second, larger meatpackers may have the market power to drive up retail prices for meat products. Finally, smaller meat processors are concerned that larger competitors will force them out of business (Ward, p. 17).

⁷ The Dickey-Fuller unit root testing results are available from the authors on request.

least squares regression techniques. Given eleven principal markets, 110 different pairwise comparisons are possible. For brevity, considerations of spatial cointegration are limited to integration comparisons between ten of the regional markets and the eastern Nebraska direct, western Kansas direct, and Omaha terminal markets. While these choices are arbitrary, these markets are interesting because of their central location and relatively large marketing volumes. In addition, this consideration allows us to examine differences in spatial price relationships between terminal and direct markets. Only the results for eastern Nebraska are reported. However, any differences between eastern Nebraska and the other markets are highlighted in the discussion.⁸

Cointegrating parameters and standard error estimates for the eastern Nebraska market are presented for each period in table 1. Each comparison is conducted under two specifications. The first specification regresses prices in each of the i regional markets on the eastern Nebraska price. The designation is reversed in the second specification with the eastern Nebraska price being regressed on each of the remaining i market prices. While the estimates of the cointegrating parameters are consistent, the verification of nonstationary price series implies that

the estimated standard errors are not consistent. This condition precludes using these results for formal hypothesis testing in regard to the value of the cointegrating parameters. However, in most cases the cointegrating parameters are close to one in numerical value. Thus, estimates of the cointegrating parameters provide informal support for spatial integration in the regional cattle markets.

The seven cointegration tests were conducted for each specification of the ten market comparisons over each of the four periods. The augmented tests were conducted with $p = 4$ lagged values of Δy_t and Δx_t .⁹ The cointegration test results for the first specification are presented in table 2. In general, the results appear to question the existence of cointegration in the regional cattle markets. Cointegration is supported by 155 of the 280 different cointegration tests for the eastern Nebraska market. As expected, cointegration is strongest for the markets which are relatively close to eastern Nebraska. However, cointegration diminishes as the distance between an individual market and the eastern Nebraska market increases. Cointe-

⁹ Lags are added to the augmented tests to ensure white noise in the residuals. Akaike's *FPE* criterion indicated lag orders of four or less in nearly every case. For the few cases for which a higher lag order was indicated, standard likelihood ratio tests confirmed that four lags were sufficient to ensure whitened residuals. Thus, we follow Engle and Granger and utilize a lag order of four for the augmented cointegration tests.

⁸ Detailed results for the other markets are available from the authors upon request.

Note: Eastern Nebraska is the central market. Critical values (Engle and Granger) are at the 5% level. An asterisk denotes rejection of the null hypothesis of no cointegration at the 5% level.

gration is strongest between eastern Nebraska and the Omaha, St. Paul, Sioux City, Iowa–Southern Minnesota, Illinois, and Lancaster, Pennsylvania, markets. In each of these cases, seventeen or more of the twenty-eight tests across the four time periods reject the null hypothesis of no cointegration. The Texas Panhandle, California, and western Kansas markets display limited cointegration with the eastern Nebraska market, with ten or less of the twenty-eight tests supporting cointegration. Schroeder and Goodwin and Koontz, Garcia, and Hudson found that price changes in eastern Nebraska and Iowa lead price changes in Illinois, Lancaster, Omaha, St. Paul, Sioux City, and other markets. This result

is consistent with cointegration among these markets.

The western Kansas direct and Omaha terminal markets had results similar to those of eastern Nebraska. Of the 280 cointegration tests, 111 supported cointegration with western Kansas and 176 supported cointegration with Omaha. The western Kansas market was primarily cointegrated with the nearby Colorado and Texas markets. The Omaha market was mostly cointegrated with the same markets as eastern Nebraska.

An important result regarding the behavior of regional market linkages over time is also revealed in table 2. The degree of cointegration

in regional cattle markets appears to have increased over the past several years. In the first two periods (1980–81 and 1982–83), only thirty-four of the seventy cointegration tests support cointegration. However, in the 1984–85 and 1986–87 periods, respectively, thirty-eight and forty-nine of the seventy tests support cointegration. These results suggest that regional market cointegration was enhanced during a time when concentration of the beef industry was increasing.¹⁰ These results were similar although less pronounced for western Kansas and Omaha.

In all, the empirical applications suggest that cointegration of regional cattle prices is limited. This may suggest that markets are segmented and arbitrage opportunities are precluded by high transactions costs or other barriers. Alternatively, the results may indicate the absence of collusive basing-point pricing behavior. However, the results also indicate that structural changes in the beef industry throughout the 1980s were paralleled by increased cointegration of spatial prices in regional direct and terminal markets. This relationship may imply increased pricing efficiency or an increased tendency toward coordinated basing-point pricing by meatpackers.

Faminow and Benson examined the behavior of price differentials in Canadian slaughter hog markets over time to provide additional evidence of basing-point pricing practices. With basing-point pricing, price differentials should reflect transportation costs and thus should increase as the distance between markets increases. Their results indicated that price differentials tended toward equality over time, suggesting the breakdown of basing-point pricing. Absolute price differentials between the eleven markets considered in this study were evaluated for each of the four periods. Although no clear trend toward equality between the price differentials was evident, the range of the price differentials did narrow across time. This result may suggest lower transportation costs and may provide additional evidence in favor of in-

creased pricing efficiency in the regional cattle markets.¹¹

Factors Influencing Spatial Price Linkages

The preceding evaluation of cointegration in spatial markets indicated that regional cattle markets are less than fully cointegrated. In this section, factors which may influence cointegration are formally assessed. A regression-type analysis of equation (9) is undertaken to evaluate the effects of market type, industry concentration ratios, relative slaughter volumes, and spatial distances on cointegration relationships. Table 3 contains the average annual slaughter volumes, distances between markets, and concentration ratios used in this analysis.

Ordinary regression estimates of equation (9) cannot directly be utilized to provide inferences regarding the influences of such factors on cointegration because the test statistic TS_{ita}^j is a generated regressand which follows a nonstandard (nonnormal) distribution. In this light, an alternative estimation strategy using bootstrapping techniques (Efron) is undertaken. Bootstrapping requires only that the residual errors be independently and identically distributed, regardless of their distribution (Prescott and Stengos). Bootstrapped coefficient estimates and standard errors can thus be used to provide consistent inferences about the variables influencing cointegration.

Bootstrapped coefficient estimates and implied *t*-ratios for each of the seven cointegration test statistics are reported in table 4. The bootstrapping estimates were obtained from 1,000 replications. The equations explained from 29% to 54% of the variation in the cointegration test statistics. The coefficient on market type is negative for six of the seven tests (three of which are significantly different from zero at the 5% level), suggesting that direct markets are less likely to exhibit cointegration with the eastern Nebraska market. This result was not consistent for cointegration test statistics obtained from the Kansas and Omaha market comparisons. The coefficient on market type was not statistically different from zero (at the 5% level) for any of the fourteen test statistics for these two markets. Thus, cointegration market linkages do not appear to differ between terminal and direct markets.

¹⁰ Cointegration test results for the alternative specification in which the designations of independent and dependent variables are reversed are not reported here. Although subtle differences exist, the overall results appear to be invariant with respect to the particular specification used in the cointegration tests. Overall, 146 of the 280 efficiency tests supported cointegration in the regional cattle markets. The same patterns were apparent in the results for the alternative market comparisons. In particular, western and southwestern markets exhibited limited spatial cointegration in linkages with eastern Nebraska and cointegration levels appeared to rise over time.

¹¹ Detailed results of the comparisons of spatial price differentials are available from the authors on request.

^a Numbers in parentheses are *t*-ratios. An asterisk indicates significance at the 5% level.^b Approximate distance from the eastern Nebraska market.

The four-firm packer concentration ratio is highly significant in most cases and is positive in every case for the eastern Nebraska market. Similar results were obtained for western Kansas and Omaha in which twelve of the fourteen coefficients on the packer concentration ratio were positive. This result suggests that increasing

concentration in the beef-slaughter industry may have been paralleled by enhanced spatial market cointegration, and thus greater spatial efficiency of regional cattle markets. Alternatively, this result may imply an increased tendency toward collusive basing-point pricing strategies in regional cattle markets.

Relative slaughter volume in the region had a negative effect on cointegration, suggesting that smaller markets exhibit a greater degree of spatial price dependence than do larger markets. The impacts of relative slaughter volume in the Omaha market were consistent with those of eastern Nebraska in that five of the seven tests had significant, negative coefficients on the relative volume variable. Conversely, none of the relative slaughter volume coefficients were significant for the western Kansas market. Finally, the most consistent result across all markets was that the degree of price cointegration between two separated markets is negatively influenced by the spatial distance between the markets. Twenty of the twenty-one coefficients on the distance variable were negative with fourteen of the twenty significant at the 5% level. This result is consistent with the decaying nature of spatial linkages over increasing distances (Mulligan and Fik).

In all, these results support prior suspicions that spatial market linkages have been enhanced by recent structural developments in the livestock industry. Increased industry concentration has coincided with greater cointegration. Regional market pricing performance also is influenced by distances between markets and slaughter volumes.

Concluding Comments

Overall, cointegration is limited in regional cattle markets. Empirical tests indicate that regional fed cattle prices have not been fully cointegrated during the 1980s. That is, the prices across different market regions have exhibited periods of moderate divergence between one another. Does this suggest market inefficiencies? Or, does this imply the absence of noncompetitive basing-point pricing practices? Finally, why are certain pairs of markets highly cointegrated while others are not? If the last question can be addressed, at least in part, then perhaps something has been learned about spatial fed cattle price relationships.

Markets separated by long distances have lower degrees of cointegration than do markets in close proximity. Markets separated by long distances are most likely linked in an indirect distance-decaying relationship through markets located between them. In this regard, a series of price changes may spread across spatial markets with a degree of lag. Given the high costs and risks associated with transporting fed cattle over long

distances, markets separated by long distances may have prices which diverge from each other for extended periods. This divergence, however, may be warranted by market conditions and may not be large enough to permit profitable trade through regional movements of cattle.

Cointegration has increased over time in the markets analyzed in this study. This increase in cointegration has paralleled increasing concentration in cattle slaughtering. Based on these results, one cannot conclude that increased concentration implies increased cointegration of markets. However, because the largest packers compete for fed cattle in the same market regions, it is reasonable that increased concentration reduces trade and information costs across markets and may contribute to spatial cointegration in the markets in which these firms compete. Moreover, packers may have coordinated price behavior across regions as market concentration has increased.

A Comparison of Video Cattle Auction and Regional Market Prices

DeeVon Bailey, Monte C. Peterson, and B. Wade Brorsen

The number of cattle sold through video auctions has increased substantially during the past five years. The nation's largest video cattle auction offered over 450,000 cattle for sale in 1988. This study compares price differences between the nation's largest satellite video cattle auction and three large regional auctions. Prices for both the regional and video auctions were adjusted for quality differences, transportation costs, commissions, and days to delivery. Net prices paid by buyers and received by sellers in video auctions exceeded the prices for three major regional auction markets.

Key words: cattle, regional auctions, transactions costs, video auction.

Video auctions are selling increasingly large numbers of cattle. Superior Livestock Auction (SLA), the nation's largest satellite video cattle auction, sold more than 270,000 cattle in 1987 and more than 450,000 in 1988. The SLA is projected to be the largest cattle auction of any kind by 1990 (Scharlier).

Acceptance of any pricing method depends on the motivations of buyers and sellers (Buccola). Sellers will want to use video cattle auctions if they provide relatively high prices and a reliable market. Economic theory suggests that video auction prices may indeed be higher than traditional auction prices. Satellite video auctions reduce travel time and expense for buyers who can bid from remote locations. Video cattle auctions can also reduce buyers' search time since they can offer a large number of cattle quickly.¹ For example, SLA offered over 90,000 cattle for sale during a two-day auction in 1988 (Scharlier). Using video auctions reduces health problems because cattle are not mingled with those from other lots and are transported to only one destination.

Despite these benefits, many buyers and sellers, as well as institutions, are concerned about the economic viability of the video auction as opposed to that of more traditional auctions. For example, because of a state policy requiring economic need or benefit to be demonstrated before licensing new cattle auctions, North Dakota refused a business license to SLA in 1986. At that time no statistical evidence was available to document the benefits of video cattle auctions. In addition, buyers and sellers are concerned about prices of the cattle sold through video auctions relative to prices in other markets.

The effect of electronic marketing systems' on structure and relative prices has been studied extensively (Sporleder; Sporleder and Mahoney; Ward; Rhodus, Baldwin, and Henderson and others). However, no study has examined relative prices of satellite video cattle auctions and traditional auctions.

Visual information provided by video auctions may be superior to the information about standard grades and quality factors provided by electronic markets. This may partly explain the general failure of electronic livestock markets while electronic marketing of alfalfa hay and cotton has been successful. Also, because video auctions operate similarly to traditional livestock auctions, buyers may feel more comfortable with them than with other electronic markets.

This paper compares the prices received for cattle sold through video auctions with prices received for cattle sold in three large traditional regional auctions. It also provides previously

¹ Other procurement costs include transportation costs, commissions to order buyers, travel costs, subscription fees, salaries, and other search costs.

unavailable descriptive information about video cattle auctions.

Description of Video Cattle Auctions

Video auction cattle presentations consist of two components—the video or visual component and the sales catalogue or written component. A \$2.00 per head videotaping fee is included in the sales commission unless the seller rejects the bid, in which case the seller forfeits the taping fee. The taping is done by one of SLA's regional representatives. Thus, the integrity of the video auction is heavily dependent on the integrity of its regional representatives. Sales catalogue descriptions are prepared by the video auction company and the seller when the cattle are videotaped.

Videotapes of about two-minute duration are shown while an auctioneer solicits bids. Buyers must register in advance of the sale and undergo a credit check in order to participate. Buyers may bid either in person or by telephone from any location where the satellite transmission can be received. SLA used two separate central locations (Denver and Ft. Worth) for its auctions in 1987, with most fall sales held in Denver and all others in Ft. Worth.

The video auction representative oversees delivery. Completed sales become cash forward contracts since all cattle are sold for future delivery. Although the video auction representative is responsible for ensuring contract compliance by both buyer and seller, buyers are permitted to be present at delivery and may attempt to influence which cattle are actually delivered. This may be a problem if prices decline before delivery. SLA believes that most larger volume buyers hedge their cattle purchases, but smaller buyers may not. Consequently, most of the few disputes that have arisen at delivery are with small volume purchasers (J. Odle, Superior Livestock Auction, personal communication, Jan. 1990).

Reasons for Price Differences between Market Types

Markets for specific agricultural commodities differ by space, structure, time of delivery, and quality (Buccola, Schroeder et al., Janssen and Shane, Bailey and Brorsen, Faminow and Gum, and others). Differences examined here are due to the markets, not to space, quality, or time of delivery.

Several differences between video and regional auctions suggest video auctions may sell cattle at prices higher than regional auction prices. The most obvious difference affecting prices is in transactions costs (transportation, shrink, and commissions). If transactions costs are low, sellers could actually receive a relatively high net price in a particular market at the same time buyers pay a relatively lower net price in the same market. If lowered transactions costs reduce their net prices, buyers may bid higher at video auctions than they would at regional auctions.

Cattle sold through video auctions do not need to be shipped to a central location as they do for regional auctions. This saves on both trucking costs and shrink. Video auctions may also have a more competitive market structure than traditional auctions have. More buyers and sellers usually participate in SLA auctions than in the regional auctions, which is indicative of the large area served by SLA and its relatively large sales volume (table 1). Hamm, Purcell, and Hudson found anonymous bidding such as the video auction uses tends to increase cattle prices. Larger sales volumes and anonymous bidding suggest prices at the video auction may be higher than traditional auction prices.

Feedlot operators often perceive cattle sold through traditional auctions as being "severely stressed and breaking with disease immediately upon or soon after arrival" at the feedlot (Pollreis, p. 24). Cattle bought directly from the farm tend to have fewer health problems than cattle sold at regional auctions (Pate). Buyers should be willing to pay higher prices for healthy cattle than for severely stressed cattle.

Video auction catalogues provide buyers with important information usually unavailable in traditional auctions, including vaccinations received, place of origin, and current feed (see fig. 1). This information could reduce buyers' death losses, reduce veterinary costs, and increase feedlot efficiency.

Video and Regional Auction Data Collection and Analysis

The 1987 sales catalogue data and accepted bid prices for each lot of cattle were gathered from the SLA. In 1987, more than 335,000 head were offered for sale via fourteen satellite video cattle auctions (table 2). SLA prices were compared to prices at three regional markets.

The Oklahoma City, Oklahoma (OKC); Greeley, Colorado; and Dodge City, Kansas, re-

Table 1. Average Number of Buyers and Estimated Commissions for Regional and SLA Auctions, 1987

	Day of the Week Most Sales Held	Average Number of Buyers Viewing Auction	Major Buyers Attending ^a	Sales Commissions and Other Deductions For Yearling Steers

^a Buyers who frequently buy relatively large numbers of cattle.

^b Estimates provided by SLA.

^c Average number of registered buyers with SLA. Of this number, 60–80 will actually buy cattle at an average sale. During 1988, 1,507 sellers consigned cattle to SLA and 372 different buyers purchased cattle.

^d The \$1.50 per head is estimated cost of beef board deduction and inspection.

^e Estimates provided by Oklahoma National Stockyard Company for yearling steers, (personal communication, May 1989).

^f Estimates provided by Greeley Producer Livestock Auction, Greeley CO (personal communication, May 1989).

^g Estimates provided by Dodge City Winter Feeder Cattle Auction, Dodge City KS (personal communication, Feb. 1990).

gional auction markets were selected for price comparisons with SLA based on their sales volume, proximity to high-density feeder cattle populations, and the availability of reliable price data. As shown in table 1, the highest volume sales days for the OKC, Greeley, and Dodge City auctions were Monday, Tuesday, and Wednesday, respectively. Most SLA auctions were held on Saturdays in 1987.

U.S. Department of Agriculture (USDA) personnel report price ranges by sex for 100-pound increments at the OKC, Greeley, and Dodge City markets. The reporters estimate the price range for a given weight and grade class by attempting to identify a price pattern within that class. If lots do not fit the reporter's established subjective pattern for the grades (i.e., No. 1 or No. 2

steers), then the prices for these cattle are either reported separately as a "package" or not reported. Bid prices for cattle that are sick, over filled, have physical defects or excessive hair or dirt, dairy or other "non-typical" breeds are also excluded by USDA reporters when price ranges are established (USDA AMS, Market News Div., Greeley CO and Oklahoma City OK, personal communications, 1989). SLA's sales catalogue reported no cattle with physical defects or excessive hair or dirt. All lots of dairy cattle were eliminated from the SLA data to maintain consistency between SLA's reported prices and those reported by USDA for the regional auctions.

The midpoints of USDA's reported price ranges at the regional auctions on their highest sales volume day of the week are compared to

LOT #1410

75 STEERS

LOCATION: Woodruff, UT—393 miles W of Cheyenne, WY.

DESCRIPTION: Herefords. BWF. Blacks and a few BeefMaster cross.

ORIGIN: Native

FRAME: Medium

EST. WT. VAR.: Uneven

FEED: Pasture with no supplement of any kind.

DELIVERY DATE: Oct. 1–10, 1987. Seller's option.

WEIGHING COND: Cattle will be gathered into dry lot by 8:00 A.M., hauled 15 miles. Unloaded and weighed in Ross Jackson scales in Randolph, UT. on the ground with a 2% pencil shrink.

SLIDE: .03 over 725 lbs.

COMMENTS: Steers have not been implanted. A nice set of light yearling steers.

REPRESENTED BY: Jerry Goodwin

Arlo Eastman

BASE WT:700#

FLESH: Medium to Light

HORNS: None

PRICE _____ BUYER _____

the bid prices actually accepted by sellers at SLA (USDA AMS 1987). For example, price comparisons for steers sold through SLA weighing between 600 and 699 pounds were made against the midpoint price for 600- to 700-pound steers at the three regional markets during the week following each SLA auction, while video auctioned steers weighing from 700 to 799 pounds were compared to the reported regional midpoints for 700- to 800-pound steers.²

Method for Expressing Seller and Buyer Prices

Transactions costs such as trucking and shrink, commissions (usually paid by the seller), and other price and/or weight adjustments, such as pencil shrink, cause seller's and buyer's prices to differ.³ Consequently, prices are examined from both the seller's and buyer's point of view. Since costs are not equal across markets, net

prices are derived and used for comparisons. The expected net price per hundredweight received by sellers and paid by buyers in any particular market can be expressed by the following equations:

$$(1) \quad SNP_i = BP_i(1 - PS) - STC - C,$$

$$(2) \quad BNP_i = BP_i(1 - PS) + BTC,$$

where SNP_i and BNP_i are the seller's and buyer's net prices, respectively, for the i th lot of cattle. BP_i is the successful bid or buy price offered by the buyer to the seller, PS is the percentage pencil shrink in decimal form or any other systematic adjustment to price in a particular market. STC and BTC are transportation costs (trucking and shrink) for the seller and buyer, respectively, and C is commissions.

Video auction cattle sold in 1987 were delivered from a few days up to nine months after sale. Feeder cattle futures prices were used to adjust buyers' and sellers' net prices for different delivery dates. Futures market prices serve as a standard of price comparison in the feeder cattle industry (Just and Rauser), and cash prices adjust quickly to changes in futures prices (Oelermann et al.). The prices are adjusted using the spread between the nearby feeder cattle futures contract and the futures contract for the contract closest to but not preceding the SLA delivery date. Only prices for steers sold through the video auction weighing between 600–800 pounds were used in order to coincide weight specifications for the feeder cattle futures contract.

The seller's and buyer's net price after adjustment for transactions costs, quality, and delivery dates for cattle sold through the video auction can be expressed as

$$(3) \quad ASNP_{it} = SNP_{it} + [NBF_{t+j} - \{(FP_{f,t-1} + FP_{f,t+2})/2\}] - QD,$$

$$(4) \quad ABNP_{it} = BNP_{it} + [NBF_{t+j} - \{(FP_{f,t-1} + FP_{f,t+2})/2\}] - QD,$$

where $ASNP_{it}$ and $ABNP_{it}$ are the seller's and buyer's adjusted net prices in dollars per hundredweight for the i th lot of cattle sold at time t . NBF_{t+j} is the closing quote for the feeder cattle futures contract closest to maturity j days after each video auction where j corresponded to the number of days between the SLA and regional auction sales (i.e., $j = 2$ for OKC, $j = 3$ for Greeley, and $j = 4$ for Dodge City). $FP_{f,t-1}$ and $FP_{f,t+2}$ were the closing quotes for the preceding Friday and following Monday feeder cattle futures contract for the contract closest to but

² An examination of the reported price ranges for the three regional auctions for the weeks preceding and following each SLA sale revealed these ranges to be relatively narrow (the narrowest range was \$3.88/cwt and the widest range was \$6.38/cwt during 1987). The Dodge City data from Kansas State University revealed, after eliminating sick, physically defective, and dairy cattle, that a range of about \$10/cwt existed for the same weight categories.

³ Pencil shrink refers to a systematic downward weight adjustment on cattle designed to make weights at the seller's location approximately equivalent with regional auction weights.

not preceding the delivery date (contract f), respectively. Friday's and Monday's futures prices were used since all but one of SLA's sales were held on Saturday when no futures quote was available. *QD* represented an adjustment for any quality differences that may exist between the two types of markets.

Adjustment for Transactions Costs

The transportation costs and commissions defined in equations (1) and (2) are not equal across markets. The distance cattle were shipped after the video auction sale was obtained from SLA. Distances for the seller's location to the regional auctions and from the regional auctions to the location designated by the buyer are on SLA's shipping records. Buyer's and seller's transportation costs were estimated for cattle sold at the video auction. Transportation costs that would have been incurred by buyers and sellers had the cattle been sold at regional auctions instead were also estimated.

Buyers' and sellers' prices in OKC, Greeley, and Dodge City are compared only with prices of cattle sold through video auction that were within the assumed market areas of the regional auctions.⁴

Transportation costs include both trucking fees and shrink. Potential trucking fees were estimated as the average rates of a large western trucking firm in 1987, which were \$2.00 per loaded mile for distances of less than 150 miles and \$1.85 per loaded mile for distances exceeding 150 miles (Chuck Webb, L. W. Miller Transportation, Logan UT, personal communication, Nov. 1988). Shrink was estimated by the method given in Minish and Fox. Their shrink equation is as follows:

$$(5) \quad \text{Shrink \%} = 3.0 + .0061 (\text{MILES}),$$

where *Shrink %* is the percentage shrink, and *MILES* is the distance cattle are trucked. Seller's potential shrink losses from shipping to a regional auction were calculated as the product of the regional midpoint price for the appropriate weight range and equation (5) using the mileage (*MILES*) from the seller's location to the regional market. This figure was adjusted downward by 25% to account for reductions in

shrink when cattle are allowed to eat and/or drink after arrival at the auction and before sale (Minish and Fox).

Buyer shrink costs for cattle purchased through the video auction were calculated as the product of the video auction bid price adjusted for pencil shrink and equation (5) using the distance from the seller's location to the shipment destination designated by the buyer. This figure was then adjusted downward by 50% since excretory shrink will be gained back quickly after arrival (Minish and Fox). Potential buyer shrink costs had the cattle been purchased at a regional auction were also calculated as the product of the regional auction midpoint prices and equation (5) using the distance from the regional auction to the shipping destination selected by the buyer for each SLA lot. The shrink rate of cattle from the regional auction is expected to be only about 60% of the rate of cattle shipped to the regional auction by the seller (Norris J. Stenquist, Utah State University, personal communications, Feb. 1990). Therefore, estimated buyer shrink costs in equation (5) were adjusted downward by 70% for shipping cattle from the regional auctions. Regional auction prices (*BNP*) are adjusted downward by the percentage shrink that would have been incurred by the seller in shipment to the regional auctions. This adjustment accounts for higher prices being paid for "pre-shrunk" cattle at the regional auctions and makes prices for current delivery at the two types of markets approximately equivalent except for transactions costs differences.

Since the buyer pays transportation costs in the video auction, video auction sellers' net prices [equation (1)] need not be adjusted for shrink and trucking costs (i.e., $TC = 0$). However, the seller usually offers pencil shrink in a video auction ($PS > 0$) to make weights approximately comparable to weights at traditional auctions. Seller's net prices at regional auctions were adjusted for the potential transportation costs from the seller's location to the regional auction.

Adjustments for Quality

Concerns about possible quality differences between the markets prompted an investigation of average quality characteristics of cattle sold in the video and traditional markets. No information was available for individual lots sold in either Oklahoma City or Greeley. However, data assembled by Kansas State University provided individual lot characteristics of cattle sold at Dodge City during March and April of 1987

⁴ An industry expert estimates cattle will usually not spend more than eight hours in transit to a regional auction (Steve Reed, Western Livestock Marketing Project, personal communication, Dec. 1988). Also, comparison of prices for lots outside of the market areas yielded basically the same results that are reported in this paper. However, the variability in prices was greater.

(Schroeder et al.). An industry expert stated that there was no reason to believe that lot characteristics should vary substantially between the Dodge City and the OKC auctions (Michael Sands, Western Livestock Marketing Project, personal communication, Nov. 1988). Supporting this conclusion, average lot sizes were quite similar for the two auctions, with OKC and Dodge City averaging thirteen and twenty head per lot, respectively (USDA AMS Mkt. News Div., Greeley CO, personal communication, Nov. 1989; Schroeder et al.). The Dodge City data represented all lots sold through that auction during these months. To be consistent with both the SLA data and USDA's reporting methods for the other auctions (OKC and Greeley), Dodge City lots with physically defective or sick cattle, dairy cattle, and those with excessive mud or hair were eliminated from the study.

The process for determining the impact of quality on auction cattle prices in a particular market is well documented in the literature. A hedonic specification such as this regresses prices on quality and market characteristics in a form similar to that used by Schroeder et al. and given below

$$(6) \quad P_i = a + \sum_{k=1}^K h_k LC_{ki} + \sum_{l=1}^L g_l MC_{li} + e_i,$$

where P_i is the price of the i th lot of cattle in dollars per hundredweight, LC_k is the k th lot characteristic, MC_l is the l th market condition, a is the intercept, h and g are parameter estimates, and e is an error term.

The parameters of equation (6) were estimated for lots of steers weighing between 600 and 800 pounds that were sold through the video auction and represent the money values of differences in the individual quality and market characteristics. The vector of parameter estimates was then multiplied by the vector of average observed values for the physical attributes and market conditions of the steers sold by SLA and those sold in Dodge City. The difference between this average predicted price provided a measure of the relative difference in the price per hundredweight (cwt.) of cattle sold in the two markets (SLA and Dodge City) based on quality. This differential was also assumed for the OKC and Greeley markets.⁵

⁵ This procedure assumes the hedonic price structure is the same for all markets. The parameters of equation (6) were also estimated for the Dodge City data. The signs and magnitudes of the coefficients were basically the same as those obtained using the SLA data with the exception of lot size.

The average quality differential between the Dodge City and SLA lots was \$0.34 per hundredweight. This figure (\$0.34/cwt.) was subtracted from the video auction price to compare prices for cattle of equal quality at both the video and three regional auctions [QD in equations (3) and (4)].

Tests

A paired t -test (Chou, p. 334) was used to test for significant differences between the seller's adjusted net price at the video auction [$ASNP$ in equation (3)] and the net price that would have been received had the cattle been shipped for current delivery to a regional auction [SNP in equation (1)]. The tests were performed for cattle sold through SLA and lying within each regional market area.

A paired t -test was also performed to determine if the adjusted buyer's net price [$ABNP$ in equation (4)] was significantly different from the estimated net price the buyer would have paid had the cattle been purchased at one of the three regional auctions instead [BNP in equation (2)] and shipped from the regional auction to the destination specified by the buyer on SLA's shipment records.

Price trends were not expected to have much effect on prices separated by only three days. Also, the adjustment using futures prices in equations (3) and (4) should remove any such possible effect. Nevertheless, we conducted a fragility test of the results by comparing the regional auction prices for the week previous to the SLA auction. The overall results were unchanged. However, average regional auction prices were slightly lower for the week previous to our comparison, indicating a positive price trend. A further investigation of price trends using daily futures prices showed that prices trended upward about \$0.03 per hundredweight per day during 1987, not enough to affect the results.

Results

Table 3 gives the parameter estimates for equation (6) and video and Dodge City auction average quality characteristics of 600- to 800-pound steers. The steers sold by the video auction were slightly heavier than those sold in the Dodge City auction. Breeds were more highly aggregated for the video sales than for Dodge City sales, and 67% of video lots were predominantly English-

^a t-values are in parentheses; single asterisk denotes significantly different than zero at 10% confidence level, double asterisk denotes significantly different than zero at 5% confidence level or better.

^b Binary variable equal to 1 if a nonuniform lot, zero otherwise.

^c Binary variable equal to one if entire lot is horned and zero otherwise.

^d Binary variable equal to one if some cattle but not all in lot had horns and zero otherwise.

^e Binary variables for breed characteristics. Base was Herefords.

^f Binary variables for frame characteristics. Base was small-framed.

^g Binary variable for flesh characteristics. Base was light fleshed.

^h Denotes a significant difference between the average value for the regional and video auctions at the 5% confidence level.

exotic crosses compared to only 35% of the lots sold at Dodge City. This resulted in a small positive quality differential for the video compared to the regional auction cattle lots since English-exotic crosses received a premium over the base

breed, Herefords. Average values for frame and flesh are similar in the two markets.

A large portion of the difference in quality between the auctions resulted from differences in lot size. When a truckload of reasonably uni-

form cattle is shipped to a regional auction, they are typically sorted into smaller lots before being sold. While the average video auction lot size is 150, the largest lot sold in the Dodge City market was 116 head. Some arguments could be made that no adjustment should be made for the larger lot sizes in video auctions since the regional auction markets have no means of selling large lot sizes. The conservative approach is taken here by adjusting for lot size.

Table 4 presents the unadjusted and the estimated adjusted prices paid by buyers and received by sellers in the different markets. SLA's unadjusted prices were significantly lower than OKC and Dodge City prices during 1987 but were basically equal to Greeley prices. However, after accounting for differences in transportation costs, quality, and different delivery dates, the seller's adjusted net price was significantly higher at the video auction than at the three regional markets (table 4). The average differences among SLA's adjusted price and the adjusted prices at the other three markets were \$0.95 per hundredweight, \$3.36 per hundredweight, and \$1.48 per hundredweight at OKC, Greeley, and Dodge City, respectively. This means that, on the average, revenue from a 700-

pound steer would be between \$6.65 per head and \$23.52 per head higher through the video auction than at the traditional regional auctions.

Buyers appear willing to pay significantly higher prices for cattle purchased at video auctions than for those purchased at traditional auctions. This difference is generally smaller than the difference in sellers' prices and was \$0.66 per hundredweight at the OKC market, \$2.41 per hundredweight at the Greeley market, and \$1.69 per hundredweight at the Dodge City market. This indicates that buyers are willing to pay between \$4.62 per head and \$16.87 per head more for a 700-pound steer purchased through a video auction than for a steer purchased at a traditional regional auction.

Tables 5 and 6 report the average adjustments made to prices. These adjustments include shrink, trucking, commissions, quality, and delivery dates. The major reason sellers receive higher prices in the video auction than in traditional auctions is lower transactions costs [line (e) of table 5]. For example, adjusted seller's prices are \$1.48 per hundredweight higher for video auction cattle than for Dodge City auction cattle, while seller's transactions costs are \$1.25 per hundredweight lower for video auction cat-

Table 4. Average Adjusted and Unadjusted Prices for Video and Regional Cattle Auctions for Sellers and Buyers

Variable	Auction Market Area

^a Trucking and estimated shrink costs from sellers' location to destination specified by buyer on SLA's shipping records.

^b Trucking and estimated shrink from regional auction to destination on SLA's shipping records.

^c Pencil shrink specified in SLA's sales catalogues.

^d Estimated shrink incurred by seller if cattle had been shipped to the regional auction. This estimates the value to a buyer at a regional auction of cattle that have already experienced some shrinking.

^e Average spread basis between the nearby feeder cattle futures contract and the contract closest to SLA's deliveries.

^f Estimated quality differential between SLA and regional markets.

^g Subtracting this figure from the unadjusted video bid price yields (approximately) buyers' adjusted video price.

^h Subtracting this figure from the unadjusted regional auction bid prices yields (approximately) buyers' adjusted regional auction price.

ⁱ Seller average transactions costs at SLA \$3.15/cwt. (table 5) plus buyer transactions costs [line (a)] divided by unadjusted SLA bid price [line (b) of table 4].

^j Line (b) plus line (c) of table 5 divided by line (a) of table 4.

tle than for Dodge City auction cattle. Unadjusted video prices also reflected relatively large discounts for future delivery [line (h) in table 5].

Sellers pay about 6.1% of the value of their cattle to market them in Dodge City, 7.5% in Greeley, and 6.7% in OKC. However, sellers' transactions costs are only about 4.4% of the value of the cattle at SLA, since sellers pay no trucking in the video auction (table 5).

Buyers' transportation costs are slightly lower from the regional auctions than from the video auction, since cattle are "pre-shrunk" (table 6). Transactions costs are substantial for both sellers and buyers at regional auctions. Combined buyer and seller transactions costs for the video auction average about 8.5% of the average unadjusted bid. Combined estimated buyer and seller transactions costs average approximately 10.4% of the unadjusted bid price for the regional auctions (table 6). Transactions costs are a significant percentage of value of cattle in both types of markets (video and regional), but transactions costs are slightly lower in the video auction than in traditional auctions. This suggests that the video auction is somewhat more efficient in completing transactions than are traditional regional auctions, since cattle are usually shipped fewer miles for video auctions.

Adjusted video auction prices are higher than the OKC, Greeley, and Dodge City midpoint prices. While statistically significant, the difference in buyer prices between OKC and the video auction is small. Thus, video auction prices are basically equal to prices at what is widely recognized as the highest priced, most competitive feeder cattle regional auction. The video auction offers sellers the advantages of lower shrink than available when using traditional auctions and zero trucking costs.

Concluding Comments

Buyer and seller acceptance of video auctions is growing. Video auctions offer some unique features that should generate interest from industry, government, and the research community.

Satellite video auctions (as analyzed here) are national markets. Large numbers of cattle from numerous regional locations, with various weight and other characteristics are offered for sale. Consequently, these auctions could be a valuable source of market information.

Video auctions may provide buyers with more information about the history of cattle, type of feed, and vaccinations than traditional auctions

provide. One way of testing for relative adequacy of information within a market is to compare prices in different markets. This study found that net prices received by sellers and paid by buyers in the video auction exceeded reported regional market prices for the week following each video sale.

For many cattle producers, video auctions appear to provide higher net prices than regional auctions provide since trucking costs and shrink are reduced. Also, reduced health problems may allow buyers to offer higher prices for video auction cattle than for traditional auction cattle. Additionally, because video auctions reduce transportation costs, they represent a new source of competition with regional auctions where little within regional competition existed before. This is evidenced by the rapid growth of video auction sales volume. In fact, one concern is the impact of video cattle auctions on other markets, particularly on regional and local auctions. Video auctions are likely to shrink the market area of the regional auctions. Sellers close to the regional auctions will have lower trucking costs than those in distant locations and may still receive a higher net price in the regional market than through video auctions. Sellers with high trucking costs will find video auctions an attractive alternative to regional auctions.

Evaluating Prior Beliefs in a Demand System: The Case of Meat Demand in Canada

James A. Chalfant, Richard S. Gray, and Kenneth J. White

An almost ideal demand system for meats is estimated using Canadian data. A Bayesian approach is used to impose inequality restrictions on substitution elasticities, via Monte Carlo integration and importance sampling, in order to conform with prior beliefs about curvature and monotonicity restrictions and substitution relationships. Results are more consistent with the concavity and monotonicity restrictions from demand theory than with the added restriction that all meats are substitutes.

Key words: almost ideal demand system, Bayesian inference, inequality constraints, meats demand.

The widespread use of flexible functional forms in demand analysis has given researchers the ability to model consumer preferences with no restrictions on the nature of substitution or complementarity relationships between pairs of goods. Unfortunately, theoretical restrictions automatically met by simpler forms need not hold with flexible forms, so estimated demand systems often conflict with prior beliefs. Symmetry and homogeneity restrictions may be violated when tested, but they are generally imposed using equality restrictions on the parameters of the model.

More difficult are restrictions represented as inequality constraints. It is common to observe predicted budget shares outside the 0–1 interval, violating monotonicity, or violation of curvature restrictions, reflected in a matrix of elasticities of substitution between goods that is not negative semidefinite. Thus, the researcher who desires to approximate arbitrary preferences often ends up with an approximation that suggests that they are badly behaved.

In this paper we show how to impose the inequality constraints of monotonicity and concavity of the consumer's expenditure function, using an almost ideal demand system for per capita consumption of meats and fish in Canada. While one might expect that many of the factors affecting U.S. consumption have also been present in Canada, relative prices have not always been similar. In particular, while beef and pork are, to a large extent, freely traded between the two countries, live poultry and poultry meat are not. During the early 1970s, Canada introduced a supply management scheme under Article 11(c) of GATT. Under this scheme, domestic prices have been supported above U.S. prices through production quotas for producers within Canada and import quotas to restrict trade. As a result, some of the relative decline in relative poultry prices that has occurred in the United States since 1970 was not observed in Canada.

In addition to the inequality restrictions from consumer theory, we suggest a new set of inequality restrictions not generally imposed on a demand system, but which have a compelling motivation. It seems reasonable to expect that no pair of foods that play essentially the same role in the diet should be complements. One thinks of coffee and cream or beef and gravy, but not beef and fish as complementary items. Yet, complementarity is common when flexible forms are estimated. In many applications, an intermediate case between the rigidity of Cobb-Douglas or CES preferences and the flexible form would be desirable.

James A. Chalfant is an associate professor of agricultural and resource economics, University of California, Berkeley; Richard S. Gray is an assistant professor of agricultural economics, University of Saskatchewan; and Kenneth J. White is a professor of economics, University of British Columbia.

The authors wish to thank many individuals, without implicating them, for helpful comments and discussions on this topic, especially the referees, Julian Alston, Tulay Bayri, Charles Blackorby, Ruey-er Chang, Erwin Diewert, John Geweke, William Griffiths, George Judge, Max King, Jeffrey Perloff, Dale Poirier, Linda Robbins, Dave Ryan, Gene Savin, Dan Sumner, Terry Wales, and Nancy Wallace.

While inequality restrictions on the signs of elasticities of substitution are suggested by empirical observation, rather than the underlying theory, they seem just as important as compatibility with theory in judging the degree to which an estimated demand system conforms to prior beliefs about consumer behavior. For applications such as this one, then, the constraint that all meats are substitutes can be viewed as another requirement that any well-behaved demand system must satisfy.

We make use of a Bayesian approach based on Geweke's (1986, 1988, 1989) work. He shows how to make inferences about or impose inequality restrictions in regression models. Chalfant and White used his method to impose curvature and monotonicity restrictions on the translog cost function but did not address restrictions on individual elasticities of substitution.

There are familiar alternatives to imposing prior beliefs with the Bayesian approach. One can always search over flexible forms to find one that is consistent with the desired restrictions but with the obvious consequences for inferences once a well-behaved demand system has been obtained (Judge and Bock). Alternatively, inequality restrictions can be imposed through constraints on a maximum-likelihood estimation procedure. Unfortunately, such constraints are difficult to interpret statistically (e.g., Gallant and Golub, Hazilla and Kopp, Wolak); the usual likelihood ratio test does not apply, for instance. Even if testing the restrictions is not the goal, imposing inequality constraints in this manner is likely to yield parameter values that lie on one of the constraints. For instance, constraining a demand elasticity to be nonpositive may well produce a vertical demand curve if the constraint is binding. Thus, a constrained maximum-likelihood approach is neither intuitively satisfying nor statistically attractive.

The next section discusses the almost ideal demand system. The Bayesian approach to inequality restrictions then is described in detail, followed by the application to meats demand. The data are described and demand system estimates are obtained for curvature and monotonicity restrictions alone and then with the added restriction that all meats are substitutes.

The Almost Ideal Demand System

Demand theory suggests that the demand for a good should be a function of its price, the prices

of other goods, and income. In order to estimate demand relationships in a system of a reasonable size, it is common to invoke weak separability; choices concerning the allocation of expenditures among a subset of goods consumed are assumed to be made independently from the prices of goods outside that group. For example, the quantity of beef consumed is likely to be a function of the prices of beef, pork, chicken, fish, and total expenditure on meat but is not a function of the price of bananas.¹

Whether or not it is appropriate to assume separability for a particular demand system is an empirical question. Theory suggests that any partial demand system representing the separable parts of larger systems should satisfy the conditions of symmetry, homogeneity, monotonicity, and concavity. Indeed, one interpretation of these conditions not holding in an estimated system is that the goods included in the demand system do not make up a separable group—a relevant price has presumably been omitted. Violation of those conditions also may indicate the presence of structural change, aggregation bias, or some other specification error.

Deaton and Muellbauer suggested the almost ideal demand system as a particular representation of price-independent, generalized logarithmic (PIGLOG) preferences. Such preferences are consistent with the aggregation of individual preferences. In addition, the functional form they chose is locally flexible in the sense used by Diewert and Barnett—it can attain arbitrary values for substitution elasticities at a given set of prices.

The equations for budget shares take the following form:

$$S_i = \alpha_i + \sum_{j=1}^M \gamma_{ij} \ln P_j + \beta_i \ln (x/P),$$

where P_j is the j th good's price, x denotes total expenditure on the M goods, and P is a price index. The specification of the underlying expenditure function introduced by Deaton and Muellbauer leads to the expression

$$\begin{aligned} \ln P = & \alpha_0 + \sum_{i=1}^M \alpha_i \ln P_i \\ & + 1/2 \sum_{i=1}^M \sum_{j=1}^M \gamma_{ij} \ln P_i \ln P_j, \end{aligned}$$

¹ Except, of course, to the extent that the prices of goods outside the group under study affect the total group expenditure, perhaps in a preliminary stage of allocating expenditures to aggregates such as meats, other foods, shelter, etc.

but this model, which is nonlinear in the parameters, is usually not estimated (for an exception, see Georgantelis, Phillips, and Zhang). More common is to follow the advice of Deaton and Muellbauer and replace this expression for $\ln P$ with Stone's geometric price index

$$\ln P = \sum_{k=1}^M S_k \log P_k$$

giving rise to an approximate almost ideal demand system that Blanciforti and Green (1983a, b) termed the linear approximate model because it is linear in parameters.

For either model, a system of these share equations can be estimated to obtain parameter estimates, and simple formulas convert the parameter estimates to elasticities. The system is easily restricted to satisfy symmetry ($\gamma_{ij} = \gamma_{ji} \forall i, j$) and homogeneity ($\sum_{j=1}^M \gamma_{ij} = 0 \forall i$). The adding-up property holds, given these restrictions, provided that $\sum_{i=1}^M \alpha_i = 1$ and $\sum_{i=1}^M \beta_i = 0$. Concavity or monotonicity restrictions are more difficult because they involve multiple inequality restrictions on the parameters. For concavity, the matrix of second derivatives of the expenditure function, or equivalently, of elasticities of substitution, must be negative semidefinite. For monotonicity, predicted budget shares must all be between 0 and 1 to ensure that predicted quantities consumed are positive.² Such restrictions are difficult to impose using most econometric packages and even harder to interpret statistically.

As with other flexible functional forms, elasticities are not constant with respect to prices and expenditures. The income elasticity of demand for good i is

$$\eta_i = 1 + \frac{\beta_i}{S_i}$$

for either specification of the price index. The Marshallian elasticity of demand for good i with respect to price j in the nonlinear model is

$$\begin{aligned} \sigma_{ij} &= -\delta_{ij} + \frac{1}{S_i} \cdot \left[\gamma_{ij} - \beta_i \alpha_j - \beta_i \sum_{k=1}^M \gamma_{jk} \ln P_k \right] \\ &= -\delta_{ij} + \frac{1}{S_i} \cdot \left[\gamma_{ij} - \beta_i \left(\alpha_j + \sum_{k=1}^M \gamma_{jk} \ln P_k \right) \right], \end{aligned}$$

where δ_{ij} equals 1 when $i = j$ and 0 otherwise.

The implied compensated price elasticity (η_{ij}^*) or elasticity of substitution (σ_{ij}) can then be obtained by manipulating the Slutsky equation in elasticity form:

$$\eta_{ij}^* = S_j \sigma_{ij} = \eta_{ij} + S_j \eta_i,$$

which yields, for the elasticity of substitution,

$$\begin{aligned} \sigma_{ij} &= 1 + \frac{\gamma_{ij}}{S_i S_j} + \frac{-\delta_{ij}}{S_i} \\ &\quad + \frac{\beta_i}{S_i} \left[1 - \frac{\alpha_j + \sum_{k=1}^M \gamma_{jk} \ln P_k}{S_j} \right]. \end{aligned}$$

The term in square brackets disappears if Stone's price index is used, leaving

$$\sigma_{ij} = 1 + \frac{\gamma_{ij}}{S_i S_j} + \frac{-\delta_{ij}}{S_i}.$$

Green and Alston noted that the latter formula is obtained for the linear-approximate model only if the budget shares appearing in Stone's price index are treated as exogenous, and they offered alternative formulas to accommodate this problem. However, the Monte Carlo results in Foster, Green, and Alston show that, if the nonlinear model is viewed as the underlying demand system and the linear-approximate model is indeed viewed as an approximation, the simpler formula provides a good approximation. This can be seen by noting that for homothetic models (where each $\beta_i = 0$), the two formulas are identical, and for nonhomothetic models, the discrepancy is likely small.

A final practical advantage of the simpler formulas is that they remain consistent with the income elasticity η_i above, whereas treating the budget shares in the price index as endogenous means that the model no longer will be characterized by these income elasticities. Deaton and Muellbauer noted that these elasticities were an advantage of the almost ideal model. In the application below, the simpler formulas are used, but the method would also apply with the "true" nonlinear model or the Green and Alston formulas.

The Bayesian Approach to Testing Inequality Restrictions

An alternative approach to imposing inequality restrictions in a demand system is made possible using a Bayesian approach, which permits the

² Chapter 3 of Varian, or a comparable text, provides further details concerning the restrictions from consumer theory.

formal inclusion of such prior information. Often, prior information can be imposed by choice of functional form. An extreme case is the Cobb-Douglas utility function, which would impose all of the restrictions from consumer theory plus some less desirable ones, such as additivity of preferences and that elasticities of substitution are each one. The latter restriction might lead one to question the stability of a demand system, for instance, if substitution patterns in response to relative price changes were not consistent with the assumed elasticities. Thus, flexible functional forms are a preferred alternative.

Symmetry and homogeneity restrictions from demand theory represent prior information that is often imposed on flexible forms through equality restrictions on the parameters. Such restrictions reduce the dimensionality of the parameter space when demand systems based on these forms are estimated; the symmetry and homogeneity restrictions, for instance, provide considerable gains in degrees of freedom. Prior information taking the form of an inequality restriction is less informative than such equality restrictions, in the sense that this information serves to truncate the parameter space, rather than reduce the number of free parameters. For instance, a particular parameter θ may be restricted to be positive. Conventional approaches to estimation do not permit the formal inclusion of such information (e.g., Judge et al.), and most econometric packages do not permit such restrictions to be imposed.

The problem of prior beliefs that take the form of inequality constraints is easily handled in the context of Bayesian inference. The Bayesian approach begins with a prior density function, defined over the vector of parameters, θ , call it $p(\theta)$.³ This prior density summarizes all of the information the researcher has about θ prior to estimation. Specifying $p(\theta)$ permits the formal inclusion of information about the parameters. For instance, if a particular parameter is considered equally likely to be positive or negative, a zero median characterizes the marginal probability density function used to describe prior beliefs about that parameter. If there is no prior information about θ , $p(\theta)$ is simply defined to be proportional to a constant over all real numbers, thus making it an improper density and a

so-called "diffuse prior." Alternatively, $p(\theta)$ could be a proper density function that reflects various beliefs about θ in the form of probability statements. A very simple case is the prior p.d.f. which says that θ is contained in some region D with probability one:

$$p(\theta) \propto c \quad \forall \theta \in D,$$

where \propto denotes "is proportional to"; D may be an open or closed interval, depending on the application. We consider below how such a prior density can be used to represent prior information about the parameters of a demand system.

Bayes' theorem shows how to combine prior and sample information to obtain a posterior distribution for the parameters in θ given a data set y :

$$f(\theta|y) \propto p(\theta) L(\theta|y),$$

where $L(\cdot)$ is the likelihood function based on the observed data. Unlike the sampling-theoretic approach to estimation, the Bayesian approach recognizes that posterior beliefs are conditional on the observed data set rather than emphasizing the performance of estimators in repeated samples.

The posterior distribution $f(\theta|y)$ summarizes all information available about θ , both prior and sample information. It can serve as the end result of an investigation, or it can be used to calculate confidence intervals and probabilities related to hypotheses about θ or to obtain a point estimate of θ or some related quantity such as a demand elasticity. The optimal point estimate for θ depends on the investigator's objective function. Constrained maximum-likelihood estimation, which yields the mode of the posterior distribution as a point estimate, corresponds to a "zero-one" loss function (e.g., Zellner 1988). This is an implausible loss function, in that it places the same weight on being wrong for estimates arbitrarily close to the true θ and for choices very far from that value. More reasonable loss functions can be imagined, and different point estimates will result. For instance, if the investigator's loss function is quadratic, the mean of the posterior distribution for θ minimizes expected loss (e.g., Judge et al.). All that is needed, then, to find Bayesian point estimates of the parameters of a demand system is a means to describe prior beliefs in the form of inequality restrictions using $p(\theta)$, a way to obtain the posterior density function, and then a way to find its mean.

Below we illustrate this approach using the quadratic loss function. With the inequality re-

³ See Zellner (1971) or Judge et al. for much more detailed descriptions of the properties of the Bayesian approach. An excellent introduction to inequality restrictions in the Bayesian framework is provided by Griffiths.

restrictions imposed, it is straightforward to obtain the mean of the posterior distribution, call it $\bar{\theta}$. This serves as the optimal point estimate of the parameters of the demand system.

Also of interest is some measure of the plausibility of the restrictions, given the data. Suppose prior beliefs are completely uninformative; that is, all parameter values are considered equally likely. In this case, the sample information dominates the posterior density function and an optimal point estimate is the mean of the (unrestricted) posterior distribution. The probability that the restrictions are correct can be calculated using the unconstrained posterior density. This probability is interpreted as the degree of belief that the restrictions are true, based on observed data, found by obtaining the probability that θ lies in D .

Both restrictions on the signs of substitution elasticities and restrictions on the entire matrix of substitution elasticities, to satisfy curvature restrictions, can be examined by calculating substitution elasticities. To evaluate these inequality restrictions, then, the behavior of elasticities of substitution must be examined everywhere in the parameter space where the researcher wishes to impose them. Similarly, the monotonicity restriction can be evaluated using predicted budget shares. Each set of restrictions is then imposed by truncating the parameter space so that each restriction holds. To obtain a Bayesian point estimate (with a quadratic loss function), the researcher must find the mean of the truncated posterior distribution for the parameter vector.

While these calculations are in principle straightforward, requiring that integrals over the posterior density function be evaluated, the analytic solutions cannot be obtained in practice, except for fairly simple models. The dimension of the posterior density is likely to be too great, even if the density function and the region of the parameter space of interest can be described easily. Instead, it is necessary to evaluate the integrals using Monte Carlo integration. This permits estimating the solutions to integrals by random sampling.⁴

To describe the method, we begin by specifying a data-generating process. We assume that prices and expenditures may be treated as exogenous, so that the parameters of the system

of $M - 1$ equations for budget shares could be estimated using seemingly unrelated regressions (SUR). As is well known, the equation for the M th budget share cannot be included without implying a singular contemporaneous covariance matrix for the error terms in the M share equations (Earten), but deleting the M th share and using restrictions on the parameters allows the complete set of parameter estimates to be obtained. Use of iterated SUR was shown by Barten to lead to maximum-likelihood estimates that are invariant to the equation chosen for deletion.

We assume that each time period's $M - 1$ vector of errors, and therefore the vector of budget shares, follows the multivariate normal distribution. Strictly speaking, one might prefer a distribution more compatible with the fact that observed shares are bounded by 0 and 1 (e.g., Woodland, Rossi), in which case imposing monotonicity is not an issue, but we prefer to stick with the more widely used distribution to illustrate the method. Our approach could easily be adjusted for nonnormal errors.

To illustrate Monte Carlo integration, suppose that Σ , the variance-covariance matrix of the errors, is known. Suppose also that $p(\theta)$, the prior information about the α_i 's, γ_{ij} 's, and β_i 's, indicates that some region D , a proper subset of R^J , contains the true parameter vector, where J denotes the number of free parameters in the model and R^J denotes the J -dimensional real numbers. Finally, suppose that the investigator has a quadratic loss function, and desires a point estimate of θ ; as noted earlier, the mean of the posterior density for θ minimizes expected loss.

The steps involved in finding an estimate of the mean, $\bar{\theta}$, are straightforward. With no prior information about θ and a known Σ , the posterior distribution for θ estimator would be the multivariate normal, centered at $\hat{\theta}$ with variance-covariance matrix $V(\hat{\theta})$, where $\hat{\theta}$ and $V(\hat{\theta})$ are obtained using Σ -restricted SUR. Given the prior information, the posterior distribution for θ then becomes the truncated multivariate normal, since θ is known to lie in D . The task becomes finding the mean of a truncated, J -variate normal:

$$E(\theta) = \int_{\theta_1 \in D} \dots \int_{\theta_J \in D} \theta N_J[\theta | \hat{\theta}, V(\hat{\theta})] d\theta_1 \dots d\theta_J.$$

Needless to say, such a calculation is infeasible for all but trivial examples.

Monte Carlo integration is based on the idea that an expectation such as the one above can

⁴ Kloek and van Dijk, van Dijk and Kloek, and Geweke (1986, 1988, 1989) provide the foundations for the Monte Carlo integration and importance sampling, described below. The application to demand systems follows the discussion in Chalfant and White. Gallant and Monahan; and Barnett, Geweke, and Yue have also followed a Bayesian approach to demand system estimation.

be estimated (arbitrarily accurately, given the Law of Large Numbers) using random sampling. One way of estimating the mean of a random variable with p.d.f. $f(\theta)$ is to generate a large number of replications in a random sample from that distribution, and calculate

$$\bar{\theta} = \frac{\sum_{i=1}^N \theta_i}{N},$$

where N is the number of replications. $\bar{\theta}$ serves as an estimate of $E(\theta)$, of course. Since N is determined by the investigator, $E(\theta)$ can be estimated with an arbitrarily high degree of accuracy. To apply that approach using the multivariate normal would require five steps:

(a) Estimate the parameters of the share equations, obtaining $\hat{\theta}$ and $V(\hat{\theta})$.

(b) Treat these as parameters of the posterior distribution for θ that would be consistent with no restrictions on θ 's range, the J -variate normal density.

(c) Use $N_J[\hat{\theta}, V(\hat{\theta})]$ and a random number generator to obtain a random sample from this multivariate normal. Omit those draws θ_i which are not contained in D , leaving a random sample of size n from the truncated multivariate normal.

(d) Estimate $E(\theta)$ using the average of the n replications in D :

$$\bar{\theta} = \frac{\sum_{i=1}^n \theta_i}{n}.$$

(e) A byproduct of the procedure is that $\hat{p}_D = n/N$ estimates the area under the multivariate normal density contained in D , i.e., the probability that the restrictions hold, given no prior information. If either p_D or $E(\theta)$ are estimated with less than the desired precision, increase N and repeat the process.

While somewhat computer-intensive, these steps are certainly feasible. They can be performed using the commonly available statistical packages for any desired posterior distribution. All that is required is a random number generator and some simple calculations.

Importance Sampling for Exact Results

The procedure outlined above relies on the asymptotic properties of the estimation procedure by making use of a normal approximation, since the covariance matrix Σ will invariably be unknown. While this is comparable to what is

done using non-Bayesian approaches, it will not yield results consistent with the exact posterior density function. Unfortunately, the posterior distribution for θ is no longer of the multivariate normal form when the variance matrix Σ is unknown. Effectively, the procedure outlined above substituted a conditional distribution $f(\theta|y, \hat{\Sigma})$ for the marginal distribution $f(\theta|y)$.

Such a marginal distribution for θ can be obtained from a joint posterior density for θ and the parameters of Σ by integrating over a posterior density for Σ . Following Zellner (1971, p. 242), Judge et al. (p. 478), or Srivastava and Giles, with a diffuse prior density for both Σ and θ , the resulting posterior density for θ is given by

$$f(\theta|y) \propto |A|^{-T/2},$$

where T denotes the number of sample observations. A typical element a_{ij} of the $M - 1$ by $M - 1$ matrix A is given by

$$a_{ij} = [(e_i(\theta))'(e_j(\theta))],$$

where $e_i(\theta)$ is the vector of residuals for share equation i evaluated using any value of θ where the posterior density is defined. This density function corresponds to the posterior density for θ with no prior information about likely values. Should one wish to impose the restriction that θ could take on only values consistent with the inequality restrictions, a truncated version of this posterior density must be used. In this framework, imposing the Bayesian restrictions and finding a posterior mean $\bar{\theta}$ requires sampling from the truncated density $f^R(\theta|y)$, but this is not a familiar density, so it is difficult to obtain an appropriate random sample. The procedure outlined above, whereby the untruncated density $f(\theta|y)$ could be used, also cannot be applied, for the same reason.

Instead, the steps outlined above must be modified, correcting for the fact that the multivariate normal is at best only approximately the correct posterior density. The technique for doing so is called importance sampling (e.g., Kloek and van Dijk, van Dijk and Kloek, Geweke 1986, 1988, 1989). The concept which underlies importance sampling is relatively straightforward. Before returning to the problem at hand, its use is illustrated with a simple example.

Consider estimating the mean of Z , a beta random variable with $\alpha = 9$ and $\beta = 1$ and density function $f(z)$. Such a random variable has

$$E(Z) = \int_0^1 z f(z) dz = \frac{\alpha}{\alpha + \beta} = .9.$$

Of course, this is an example where the integral could be evaluated and where random draws can also be obtained from the correct distribution, but suppose that we had available only a uniform random number generator, whose density function we denote $g(z)$. How might the mean of the beta distribution be calculated, using random draws from $U(0, 1)$?

The sample mean of replications drawn from the $U(0, 1)$ will underestimate $E(Z)$ because it will tend toward one-half. The reason, of course, is that values close to zero for Z occur more often under $U(0, 1)$ and most values above one-half will occur less often than under the beta distribution we have chosen. Importance sampling corrects for this by adjusting the "importance" given to each replication. The appropriate weight for each replication z_i is the ratio of the probability density function of the beta distribution at z_i , $f(z_i)$, and the density of the uniform at z_i , $g(z_i)$. In this way, those values drawn which are closer to one will receive a large weight while those closer to zero will receive a smaller weight.

To see why this works, note that the expected value of Z using the density function given by $f(z)$ can be found by integrating over $g(z)$ instead:

$$E(Z) = \int z f(z) dz = \int z \frac{f(z)}{g(z)} g(z) dz.$$

In the first instance, $E(Z)$ is taken with respect to f ; and in the second, $E[Z f(Z)/g(Z)]$ is taken with respect to g . Just as $E(Z)$ could be estimated using a sample mean of replications from $f(z)$, then so could it be estimated by drawing from $g(z)$ and calculating

$$\frac{\sum_{i=1}^N z_i \frac{f(z_i)}{g(z_i)}}{N}.$$

One surprising aspect of this procedure is that any density function can be used as $g(z)$, provided it is strictly positive over the range of Z determined from $f(Z)$. Otherwise, division by $g(z)$ within the integral is not allowed, and the implication would be that some values of Z , which do occur when sampling from $f(z)$, would never be drawn using $g(z)$. Naturally, if the weights applied to each z_i are close to one, so that $f(z)$ and $g(z)$ are similar, fewer draws will be required to obtain good estimates of the values of these integrals (Kloek and van Dijk; van Dijk and Kloek; Geweke 1986, 1988, 1989).

This procedure can be applied for estimating

the mean of the exact posterior density for θ . The posterior distribution is analogous to the beta distribution in the case above, in that it is the correct density but difficult to work with. Meanwhile, the multivariate t will be used as was the uniform distribution, to generate replications for θ . In the case of uninformative priors, draws from the multivariate t can be adjusted by the ratio of the two density functions to obtain an estimate of the probability that the inequality restrictions hold. Alternatively, the inequality restrictions can be imposed, so that the posterior density is truncated or restricted.

To find the posterior mean, find the solution to

$$E(\theta|y) = \int_{\forall \theta \in D} \theta f^R(\theta|y) d\theta.$$

At the same time, to calculate the probability that the restrictions hold, find

$$p = \int_{\forall \theta \in D} I(\theta) f(\theta|y) d\theta,$$

where $I(\theta) = 1$ if the restrictions hold and $I(\theta) = 0$ otherwise. Each of these could be accomplished by sampling from the exact posterior density $f(\theta|y)$, if it were of a known form, and the steps outlined earlier could be used. Because these integrands are too complicated to permit analytic solutions, importance sampling must be used. To reiterate, notice that the posterior mean can also be found by

$$E(\theta|y) = \int_{\forall \theta \in D} \theta \frac{f^R(\theta|y)}{g^R(\theta|y)} g^R(\theta|y) d\theta,$$

where $g^R(\theta|y)$ is the truncated multivariate t p.d.f. and D is the region of the parameter space consistent with the concavity and monotonicity restrictions. Again, the density $g^R(\theta|y)$ must be positive over the entire range (D) of the posterior density $f^R(\theta|y)$.

The modified steps now required for the calculations, taken from Chalfant and White, are given below:

(a) Estimate the parameters of the demand system using iterated seemingly unrelated regressions to obtain maximum likelihood estimates $\hat{\theta}$ and the estimated covariance matrix $V(\hat{\theta})$.

(b) Calculate ε matrix H such that $HH' = V(\hat{\theta})$. Draw a random vector of the same length as $\hat{\theta}$ from the standard normal distribution

$$w \sim N(0, I),$$

where I is the identity matrix of order J . Replications of θ that follow a multivariate t -distribution with λ degrees of freedom can be generated using the steps in van Dijk and Kloeck. We obtain

$$\theta^A = \hat{\theta} + Hw/v$$

and its "antithetic replication"

$$\theta^B = \hat{\theta} - Hw/v,$$

where v is obtained by taking a vector z of λ draws from $N(0, 1)$ and calculating

$$v = [(z'z)/\lambda]^{1/2}.$$

The inclusion of antithetic replications was suggested by Geweke (1988) to improve convergence.

Using the multivariate t ,

$$g(\theta|y) \propto \left[\lambda + (\theta - \hat{\theta})' \Sigma^{-1} (\theta - \hat{\theta}) \right]^{-(\lambda+J)/2}$$

(c) Check each replication to see if it violates concavity, monotonicity, or substitutability. To do so, we calculated elasticities of substitution using each replication and the means of observed budget shares for the four meats. Concavity and substitutability were checked using these elasticities. (To check these restrictions for all 29 observations would have involved simply repeating the same check for each observed share vector.) To check monotonicity, we used each replication to obtain new predicted shares for all twenty-nine data points.

(d) Estimate the mean of the posterior distribution using the n draws of θ^A or θ^B that satisfy the restrictions

$$\bar{\theta} = \frac{\sum_{k=1}^n \theta_k \frac{f^R(\theta_k|y)}{g^R(\theta_k|y)}}{\sum_{k=1}^n \frac{f^R(\theta_k|y)}{g^R(\theta_k|y)}}.$$

As noted by Chalfant and White, if $f(\theta|y)$ and $g(\theta|y)$ were proper density functions, a denominator of N would suffice. Otherwise, the denominator serves as a normalizing constant to correct for the fact that we use only the kernels of proper densities.

(e) To estimate the probability that the restrictions hold, use all replications, letting the first n be those consistent with the restrictions, and calculate

$$\hat{p}_D = \frac{\sum_{k=1}^N I(\theta_k) \frac{f(\theta_k|y)}{g(\theta_k|y)}}{\sum_{k=1}^N \frac{f(\theta_k|y)}{g(\theta_k|y)}} = \frac{\sum_{k=1}^n \frac{f^R(\theta_k|y)}{g^R(\theta_k|y)}}{\sum_{k=1}^N \frac{f(\theta_k|y)}{g(\theta_k|y)}}.$$

(f) Check to see if the number of replications is large enough to arrive at stable estimates of $\bar{\theta}$ or \hat{p} and of their standard deviations, if desired. If not, increase N .

A measure of the numerical accuracy of each estimated expectation, analogous to the usual standard error of the estimate of a population mean, was suggested by Geweke (1989). These can be used in step (f). The numerical standard error (nse) of the estimate of the mean of the posterior is given by

$$nse(\theta) = \frac{\sum_{k=1}^N (\theta_k - \bar{\theta}_k)^2 \left(\frac{f(\theta_k|y)}{g(\theta_k|y)} \right)^2}{\left(\sum_{k=1}^N \frac{f(\theta_k|y)}{g(\theta_k|y)} \right)^2}.$$

As also pointed out by Barnett, Geweke, and Yue, these measures are reliable estimates of the true nse's if and only if the tails of the distribution being sampled from are at least as "fat" as the tails of the posterior distribution. This characteristic of the importance sampling procedure is easily checked by plotting the replications of each θ_k against the ratio $f^R(\theta|y)/g^R(\theta|y)$. The weights should approach zero in the tails of each posterior distribution.

The standard deviation of the posterior distribution can be estimated by taking the square root of the estimated variance of the posterior distribution, obtained by using importance sampling to estimate $E[(\theta_k - \bar{\theta}_k)^2]$:

$$s.d.(\theta) = \left[\frac{\sum_{k=1}^N (\theta_k - \bar{\theta}_k)^2 \left(\frac{f^R(\theta_k|y)}{g^R(\theta_k|y)} \right)}{\sum_{k=1}^n \frac{f^R(\theta_k|y)}{g^R(\theta_k|y)}} \right]^{1/2}.$$

Application to Aggregate Meat Consumption in Canada

In this section, an almost ideal demand system for meat and fish products is estimated using aggregate Canadian data for the years 1960 to

1988.⁵ The data are from Agriculture Canada (Robbins) and were also used by Alston and Chalfant. The demands for four goods were examined—beef, pork, poultry, and fish (henceforth, the meats group). Consumer preferences for the meats group were assumed weakly separable from all other goods, and the demand system was treated as the second-stage allocation model, conditional on prices and a predetermined level of expenditures.⁶ Using the Agriculture Canada data on price indices and per capita quantities consumed for each meat, along with 1981 nominal prices reported in Van Kooten, we converted indices into current prices and calculated total expenditures on the group.

One remaining variable was included, a "trend" term taking the value 1 in 1975 and increasing by 1 in every subsequent period. Alston and Chalfant found that, although this data set is consistent with the hypothesis of stable preferences, the almost ideal demand system cannot be fit to these data without some allowance for dynamic influences; we chose the trend term as being more interpretable, albeit conditional on this specification, than an autocorrelation correction. A trend that began in the middle of the sample, 1975, seemed to correspond more to a hypothesized structural change or other type of model failure than did one beginning in 1960.

The share equations of the linear approximate form, obtained by deflating nominal expenditures by Stone's geometric price index, were then augmented by including this trend coefficient in each share equation. Thus the expression for the share of the budget allocated to the *i*th meat is

$$S_i = \alpha_i + \sum_{j=1}^4 \gamma_{ij} \ln(P_j) + \beta_i \ln(x/P) + \tau_i t.$$

A system of three such equations was estimated using the nonlinear regression (NL) procedure of version 6.1 of SHAZAM (White et al.). The fourth equation was deleted because of singularity of the variance matrix for all four equations, and parameters of that equation were obtained through the homogeneity and symmetry

Table 1. Unconstrained Results, Almost Ideal Demand System

Parameter ^a	Estimate	Standard Error
α_{beef}	-0.502	0.157
$\gamma_{\text{beef} \cdot \text{beef}}$	0.091	0.019
$\gamma_{\text{beef} \cdot \text{pork}}$	-0.004	0.012
$\gamma_{\text{beef} \cdot \text{poultry}}$	-0.009	0.013
$\gamma_{\text{beef} \cdot \text{fish}}$	-0.078	
β_{beef}	0.216	0.039
τ_{beef}	-0.0029	0.0007
α_{pork}	0.732	0.144
$\gamma_{\text{pork} \cdot \text{pork}}$	0.040	0.0145
$\gamma_{\text{pork} \cdot \text{poultry}}$	0.0162	0.017
$\gamma_{\text{pork} \cdot \text{fish}}$	-0.052	
β_{pork}	-0.010	0.037
τ_{pork}	-0.0020	0.0008
α_{poultry}	0.211	0.238
$\gamma_{\text{poultry} \cdot \text{poultry}}$	0.016	0.037
$\gamma_{\text{poultry} \cdot \text{fish}}$	-0.023	
β_{poultry}	-0.0006	0.063
τ_{poultry}	0.0032	0.0011
$\gamma_{\text{fish} \cdot \text{fish}}$	0.152	
β_{fish}	0.116	
τ_{fish}	0.0016	

^a Estimates of parameters without standard errors were obtained from the equality restrictions for symmetry, homogeneity, and adding-up.

restrictions. The adding-up property is preserved by letting the sum of the four trend coefficients equal zero. By iterating over both the parameters and the error variance-covariance matrix, the estimates obtained are invariant to the equation chosen for deletion (Barten).

Estimates of the parameters are given in table 1. The trend coefficients do appear to contribute significantly to the model, as the likelihood-ratio test statistic for the restriction that they are all zero is 35.19 (as compared with a critical value of $\chi^2_{3, \alpha=.05}$ of 11.345). They imply that, if the almost ideal model is the correct specification, there has been a negative trend affecting beef and pork and a positive one affecting chicken and fish.⁷

Elasticities of substitution are reported in table 2. Compensated price elasticities and expenditure elasticities are reported in table 3, part A, while uncompensated Marshallian elasticities

⁵ Other applications of this system to agricultural data include Blanciforti, Green, and King; Chalfant; Hayes, Wahl, and Williams; and Mcschini and Meilke. Hayes, Wahl, and Williams also consider the restriction that all meats are substitutes, in an examination of Japanese meats demand.

⁶ Although LaFrance notes that treating expenditures as predetermined is inconsistent with the assumption that quantities are measured with errors, this is standard practice. The method we use does not depend on this assumption, however, and could accommodate a joint explanation of the first- and second-stage allocation decisions.

⁷ Because the results from the nonparametric test for stable preferences were consistent with the existence of a stable demand system, the trends may be picking up misspecification of the almost ideal model. One way to decide whether one should instead disregard those results and conclude that significant trends imply structural change rather than misspecification is to analyze the implied behavior of elasticities in a variety of models. Our analysis of just one demand system cannot answer that question definitively, but the procedure followed below provides a means for such an analysis to incorporate prior beliefs.

Table 2. Elasticities of Substitution: Posterior Mean Values

Elasticity	Unconstrained	Concavity	Concavity and Substitutability
$\sigma_{\text{beef beef}}$	-1.13	-1.158 [0.003] ^a (0.188)	-1.207 [0.004] (0.181)
$\sigma_{\text{beef pork}}$	0.953	0.934 [0.003] (0.158)	0.902 [0.004] (0.156)
$\sigma_{\text{beef poultry}}$	0.853	0.797 [0.004] (0.225)	0.735 [0.006] (0.221)
$\sigma_{\text{beef fish}}$	-0.049	0.072 [0.005] (0.316)	0.252 [0.007] (0.272)
$\sigma_{\text{pork pork}}$	-2.384	-2.405 [0.005] (0.282)	-2.471 [0.007] (0.280)
$\sigma_{\text{pork poultry}}$	1.268	1.186 [0.008] (0.406)	1.087 [0.011] (0.404)
$\sigma_{\text{pork fish}}$	0.013	0.147 [0.009] (0.466)	0.375 [0.011] (0.423)
$\sigma_{\text{poultry poultry}}$	-3.641	-3.876 [0.020] (1.092)	-3.627 [0.023] (0.994)
$\sigma_{\text{poultry fish}}$	0.549	0.965 [0.019] (1.014)	0.95 [0.020] (0.835)
$\sigma_{\text{fish fish}}$	-0.458	-1.216 [0.020] (1.181)	-1.772 [0.019] (0.795)

^a The numerical standard errors of the estimated posterior means are reported in square brackets, and the corresponding standard deviations are in parentheses.

ties are given in table 4, part A. Recall that the latter make use of a constant level of meats expenditure, not total expenditure. These elasticities were calculated at the mean budget shares observed in the sample and were obtained without the inequality constraints.

The negative own-elasticities of substitution are as one would expect. The mostly positive elasticities of substitution indicate that the meats tend to be substitutes for one another at the mid-point of the sample. The unrestricted results that are contrary to prior belief are the negative elasticity of substitution, indicating complementarity, between fish and beef that is observed at the sample mean shares. Also contrary to expectations was the small positive elasticity between fish and pork and the fact that this elasticity also was often negative when the elasticities of substitution were evaluated at the individual observations.

Concavity holds at the mean and for the last eighteen observations in the sample; however,

the own-elasticity of substitution for fish is positive for the first eleven data points, violating a necessary condition for concavity. For all but six observations, at least one elasticity of substitution between two goods was negative for either beef and fish or beef and pork, sometimes both at once. Finally, monotonicity holds with these estimates at every point in the sample.⁸

Using the Bayesian procedure described earlier, the probability that the monotonicity, concavity, and substitution restrictions hold for this demand system can be estimated. We followed the procedure outlined earlier to obtain a sample size of 10,000 replications (5,000 plus the antithetic replications) from the multivariate *t*-distribution with $\lambda = 4$ degrees of freedom, again

⁸ A further indication that this model requires trend effects is that the results without the trend terms are completely inconsistent with the concavity or substitution restrictions. When the model was estimated with the trend coefficients set equal to zero and the estimated parameters were used to calculate elasticities, every observation violated both restrictions.

Table 3. Compensated Demand Elasticities

Quantity <i>i</i>	Price <i>j</i>			
	Beef	Pork	Poultry	Fish
Part A. Unconstrained Case				
Beef	-0.393	0.234	0.169	-0.010
Pork	0.331	-0.586	0.252	0.003
Poultry	0.297	0.312	-0.723	0.114
Fish	-0.017	0.003	0.109	-0.095
Expend. Elasticities	1.614	0.582	0.966	0.499
Part B. Concavity Imposed				
Beef	-0.403	0.230	0.158	0.015
Pork	0.325	-0.591	0.235	0.031
Poultry	0.277	0.291	-0.769	0.200
Fish	0.025	0.036	0.191	-0.253
Expend. Elasticities	1.575	0.537	0.832	0.745
Part C. Concavity and Substitutability Imposed				
Beef	-0.420	0.222	0.146	0.052
Pork	0.314	-0.607	0.216	0.078
Poultry	0.256	0.267	-0.720	0.197
Fish	0.088	0.092	0.189	-0.368
Expend. Elasticities	1.524	0.462	0.860	0.893

using SHAZAM. The in-sample results for $\hat{\theta}$ and $V(\hat{\theta})$ were used to specify the parameters of this distribution. Only four degrees of freedom were chosen to ensure that sampling would occur from a density with relatively "fat" tails, thereby assuring that the entire range of the actual posterior distribution is covered by the importance

Table 4. Marshallian Demand Elasticities

Quantity <i>i</i>	Price <i>j</i>			
	Beef	Pork	Poultry	Fish
Part A. Unconstrained Case				
Beef	-0.955	-0.163	-0.151	-0.346
Pork	0.129	-0.729	0.136	-0.118
Poultry	-0.039	0.074	-0.914	-0.087
Fish	-0.191	-0.119	0.010	-0.199
Part B. Concavity Imposed				
Beef	-0.951	-0.158	-0.154	-0.312
Pork	0.138	-0.723	0.129	-0.081
Poultry	-0.012	0.087	-0.934	0.028
Fish	-0.234	-0.147	0.044	-0.407
Part C. Concavity and Substitutability Imposed				
Beef	-0.950	-0.153	-0.157	-0.264
Pork	0.153	-0.721	0.124	-0.018
Poultry	-0.044	0.056	-0.891	0.0187
Fish	-0.223	-0.127	0.011	-0.554

density. Monotonicity was checked by using each replication to predict budget shares for all twenty-nine observations; every replication was consistent with positive budget shares for each observation, so monotonicity was never violated. Concavity was checked for each replication by calculating substitution elasticities using the parameter values given by each replication and the mean observed budget shares. The eigenvalues were then calculated for each matrix of elasticities of substitution.

Consistency with the concavity restriction (a substitution matrix without positive eigenvalues) was found in over half of the replications. Had we been sampling from the exact posterior, the proportion consistent with concavity would have been the estimate of the probability that concavity holds, given diffuse priors. As noted earlier, however, that probability can be estimated using importance sampling to correct for not sampling from the exact posterior. Calculation of the ratio \hat{p}_D in step (e) of section 4 yielded a value of 0.57. These results imply that the demand system is reasonably well behaved by this criterion. Table 5 summarizes all of the results in this section for the posterior probabilities that various restrictions are true.

Elasticities of substitution calculated using the concavity restriction are given in table 2, with numerical standard errors and standard deviations. The point estimates for the elasticities are obtained by estimating the means of the posterior distributions for each elasticity. Those distributions were found using the posterior distributions for the parameters, the mean budget shares, and the formulas for elasticities. The own

Table 5. Posterior Probabilities of Restrictions

Inequality Restriction	None	Concavity	Concavity and Substitutability
Concavity (n.s.e.)	0.57 0.010		
All substitutes (n.s.e.)	0.6 0.003	0.28	
$\sigma_{\text{beef pork}} > 0$	1	1	
$\sigma_{\text{beef poultry}} > 0$	0.999	1	
$\sigma_{\text{beef fish}} > 0$	0.427	0.59	
$\sigma_{\text{pork poultry}} > 0$	0.599	1	
$\sigma_{\text{pork fish}} > 0$	0.507	0.63
